## **ABSTRACT**

This thesis presents an OPNET model and simulation of a single cell wireless communications system within a proposed expeditionary warfare communications network. The focus of this thesis is to model and implement data and voice traffic generation, slotted ALOHA medium access control protocol, and direct sequence spread spectrum code division multiple access (CDMA) mechanisms in OPNET. The RF channel is modeled as both a Rayleigh fading channel and a non-fading noise limited channel. Simulation results evaluating the induced BER and multiple access implementation are presented.

## I. INTRODUCTION

The direction of both the Navy and Department of Defense has changed over the past few years, with an increased emphasis on expeditionary warfare and littoral operations [1,2,3]. Air-to-ground and ship-to-shore communications are a necessity for littoral operations. A conceptual network which could provide the necessary communications backbone for littoral operations is proposed as portrayed in Figure 1 [4]. The conceived network supports this requirement with a series of routers interconnecting the sea-based forces, aerial elements, and the mobile warfighters ashore.

In an effort to determine the feasibility of this network, this thesis develops a model and simulation of the communications link between the ground based warfighter and an interconnecting router. The link is modeled as a single cell within the network.

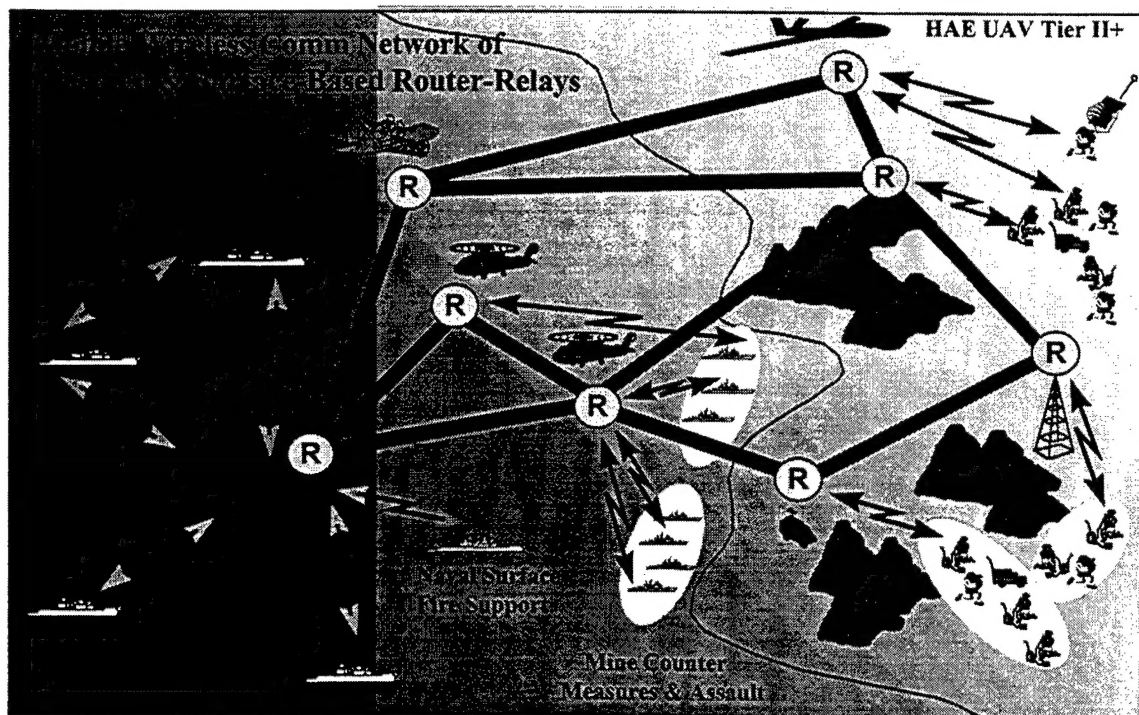

Figure 1. Proposed Expeditionary Warfare Communications Network [from [4]]

## **A. OBJECTIVES**

The objective of this thesis is to develop an OPNET model and simulation of the communications uplink for the proposed system shown in Figure 1. The modeling tool used is MIL 3 Inc.'s Optimized Network Engineering Tool (OPNET), version 3.0.A. This effort concentrates on the medium access control (MAC) layer and the physical layer. The model incorporates data and voice traffic sources. Medium access control is implemented with the slotted ALOHA protocol. The physical layer is implemented as a spread spectrum code division multiple access (CDMA) system. The system is simulated in OPNET and the bit error rate and channel utilization performance results are presented.

## **B. ORGANIZATION**

This thesis is organized as follows. Chapter II provides the theoretical background for the model. Chapter III addresses the implementation of the transmitter. The system traffic models are reviewed, and the details of the slotted ALOHA MAC and direct sequence spread spectrum implementation are covered. Chapter IV covers the characterization of the RF channel using OPNET's pipeline stages. Chapter V outlines the implementation of the receiver and gives the specifics of multiple access reception. Chapter VI presents the simulation results and evaluates the system performance. Chapter VII concludes this effort and offers recommendations for future development.

Appendix A gives an overview of the OPNET modeling software for the reader who is unfamiliar with the package. Appendix B details the specifics of the OPNET pipeline stages. The details of the Interference, SNR, Bit Error Rate (BER), and the Error Allocation pipeline stages are explored. Appendices C through E provide the OPNET model source code for implementing the transmitter, the pipeline stages, and the receiver, respectively.

## II. BACKGROUND

This thesis concerns the modeling and implementation of the cellular environment depicted in Figure 2.1. The system is considered a single cell with  $K$  nodes. The nodes are assumed static within a cell radius of five kilometers. Power control is implied in that each node is equidistant from the receiver and all transmit equal power. The model includes voice and data traffic generation and focuses on three distinct areas: medium access control, spread spectrum code division multiple access (CDMA), and the radio channel. Figure 2.2 depicts the link between a single node and the receiver. This thesis models each functional block, and this chapter presents the theoretical basis for each block.

**Figure 2.1. Cellular System Overview:  
Base Station Encircled by  $K$  Nodes**

**Figure 2.2. Single Communications Link between Node and Receiver**

### A. TRAFFIC MODELING

The traffic considered for this system is a combination of voice and data packets generated from a user application layer. Considerable effort has been devoted to modeling both voice and data traffic [5]. Here we utilize the traffic models developed by Uziel [6].

Uziel proposes low rate models for voice, video and data. The low rate models are especially applicable in this environment because of the limited channel rate. The voice model is based on Brady's [7] Markovian model for a two-way conversation. The model in [6] is represented as a three state birth-death Markov process. It generates voice traffic at a mean rate of 75 packets/sec.

The data model [6] is represented as a hybrid three state Markov chain consisting of *inactivity*, *low activity*, and *high activity* states. The *low activity* state considers transfer of text files, email messages and such, and this activity is expected to occur frequently. The *high activity* state considers much larger data transfers such as imagery and graphics but is expected to occur much less frequently. Though both low and high active states offer the same data rates, the *low activity* state produces an average of 50 packets/burst while the *high activity* state produces an average of 1,000 packets/burst. Consequently, the model generates data traffic at an average rate of 3.85 packets/sec [6].

### B. MEDIUM ACCESS CONTROL

In this section we analyze the theoretical performance of slotted ALOHA medium access control. The performance of access contention techniques can be evaluated by the measuring the system throughput, which is defined as the average number of successful receptions per unit of time. Assuming packet transmissions have a Poisson distribution, the system throughput is defined as  $R = \lambda\tau$ , where  $\lambda$  is the mean arrival rate and  $\tau$  is the

packet duration in seconds. The normalized throughput  $T$  is defined as the total offered load to the system times the probability of a successful transmission: [8]

$$T = R \times Pr[\text{no collisions}] = \lambda \tau \times Pr[\text{no collisions}].$$

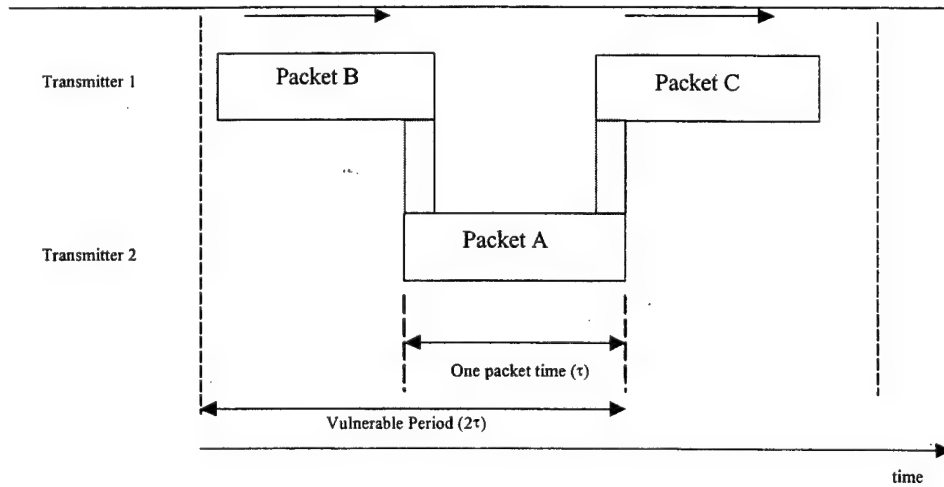

The probability that  $n$  packets are generated by the user population during a given packet duration interval, assuming a Poisson distribution, is given as

$$Pr[n] = \frac{R^n e^{-R}}{n!}. \quad (2.1)$$

The probability that zero packets are generated, thus there are no collisions, during this time interval is given by

$$Pr[0] = e^{-R}. \quad (2.2)$$

The time interval in which packets are susceptible to collisions from other packets is referred to as the vulnerable period,  $V_p$  [8]. Figure 2.3 depicts the arrival of packets and the vulnerable period  $V_p = 2\tau$  where packet collision is possible.

**Figure 2.3. Vulnerable period of packet collision [from [8]]**

## 1. Slotted ALOHA

Slotted ALOHA divides the time axis into slots of length greater than or equal to the packet duration  $\tau$ . All transmitters are synchronized and allowed transmissions only at the beginning of a slot. Although multiple packets may arrive during any slot, transmitters will only transmit one packet at the beginning of each slot. This implementation prevents partial collisions as a packet experiences either total collisions (all packets are the same length) or no collision. [9]

The vulnerable period for slotted ALOHA is  $\tau$  or one packet duration. The probability that no other packets will be generated during the vulnerable period is  $e^{-R}$ . Normalized throughput for slotted ALOHA is obtained as [8,9]

$$T = Re^{-R}. \quad (2.3)$$

The maximum throughput is found by taking the derivative of Equation (2.3), and solving for  $R$ :

$$\frac{dT}{dR}(T = Re^{-R}) = e^{-R} - Re^{-R} = 0 \quad (2.4)$$

which yields  $R_{\max} = 1$ . The maximum throughput of the slotted ALOHA system can be found by substituting  $R_{\max} = 1$  into Equation (2.3):

$$T = e^{-1} = 0.3679.$$

## C. SPREAD SPECTRUM

In this section we review the spread spectrum concepts of code division multiple access (CDMA) techniques. Direct sequence (DS) and frequency hopping are two common techniques. Here we consider DS CDMA only. For a detailed study of spread spectrum techniques, the reader is referred to [10].

## 1. Direct Sequence Spread Spectrum

Implementing DS spread spectrum requires the generation of a pseudo-random signal (PN sequence) resembling a binary wave form, followed by the spreading of the information signal with the generated sequence.

### *a. Generating the PN Sequence*

PN sequences (codes) are typically generated using sequential logic circuits consisting of a shift register of  $n$  stages (*degree  $n$* ) and a feedback loop. We focus on linear feedback shift-registers as depicted in Figure 2.4. The shift register is initialized with an initial binary load. With each clock pulse, the binary sequences are shifted through the register, and the output of selected stages of the register are tapped and fed back to the feedback logic. The feedback logic consists of an exclusive-OR gate, whose output becomes the input to the register.

**Figure 2.4. Five Stage Linear Feedback Shift Register for Generating PN Sequences**

If the initial condition (IC) of the shift register in Figure 2.4 is set with a binary sequence that causes the register to cycle through all possible ( $2^n$ ) states, the PN sequence generated is known as a *maximal length sequence* (ML) or *m-sequence*. The all zeros state is not allowed. Thus, an *m-sequence* shift register produces  $2^n - 1$  states.

The feedback taps of the shift register can be described as the characteristic polynomial. The polynomial characterizing the feedback in Figure 2.4 is  $1 + D^3 + D^5$ .

This characteristic polynomial can be denoted  $R(x_i)$ ,  $i = 1, 2, \dots, n$ , where  $x_i$  indicates the feedback stages. For example,  $R(3, 5)$  fully describes the register of Figure 2.4. [10, 11].

Not all polynomials produce  $m$ -sequences. Those that do are known as *primitive polynomials*. The number of primitive polynomials of degree  $n$  is found from [10]

$$N_p = \frac{2^n - 1}{n} \prod_{i=1}^J \frac{p_i - 1}{p_i} \quad (2.5)$$

where  $J$  is the number of prime factors and  $p_i$  are the prime factors of  $2^n - 1$ . As an example, consider the shift register of Figure 2.4. The only prime factor of  $2^5 - 1$  is 31. Thus,  $i = J = 1$ ,  $p_1 = 31$ , and  $N_p = 6$ .

### b. Spreading the Signal

Spreading the information signal is accomplished by the multiplication of the information signal with the PN sequence as depicted in Figure 2.5. The message sequence and the PN sequence must be transformed from normal binary sequences to sequences of +1s and -1s. The resultant signal is modulated with a carrier and becomes the actual transmitted signal.

**Figure 2.5. Simplified DS-SS Transmitter [from [8]]**

Figure 2.6 depicts an information signal waveform and the corresponding PN sequence waveform generated using the configuration of Figure 2.4 with an initial load of 00101. The PN sequence is multiplied with the information signal. The resulting signal is equivalent to the PN sequence for all data bit 1s and the inverse of the PN sequence for

all data bit 0s.  $T_b$  is the time duration of the data bit pulse, and  $T_c$  is the time duration of the PN code pulse, often referred to as *chip duration*.

**Figure 2.6. Information and PN Sequence Waveform**

As seen in Figure 2.6, this implementation produces 31 chips per information bit. The information bit rate  $R_b = 1/T_b$  and the chip rate  $R_c = 1/T_c$ . Defining  $k = 2^n - 1$ , the number of chips per bit, we have

$$T_b = kT_c \quad (2.6)$$

or equivalently

$$R_c = kR_b. \quad (2.7)$$

The information data bits are spread with the complete PN sequence, such that the PN sequence repeats completely every bit interval. Such an implementation is referred to as one based on *short codes*. Spreading of the information bits results in what is termed as the *processing gain* of the system and can be shown as [Sklar]

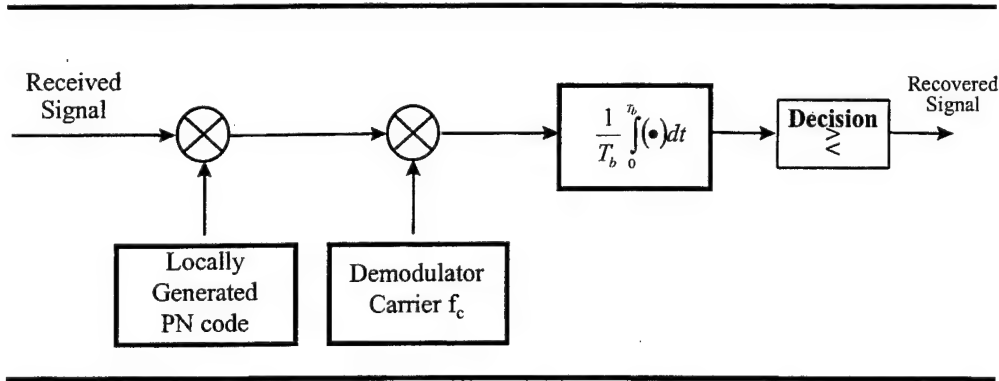

$$G_{DS} = \frac{B_{ss}}{B} \quad (2.8)$$

where  $B_{ss}$  is the spread spectrum bandwidth and  $B$  is the minimum bandwidth of the data, normally taken to be the data rate  $R_b$  [10,12]. For short codes, *processing gain* can be equivalently expressed as [11]

$$G_{DS} \text{ (dB)} = 10 \log_{10}(k). \quad (2.9)$$

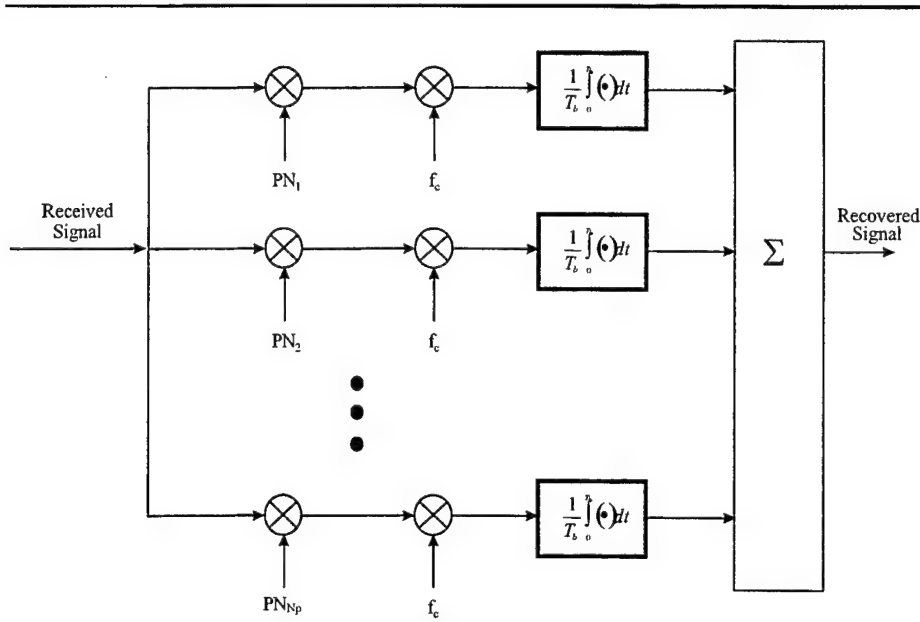

### c. Despreading the Signal

The receiver's objective is to recover the spreaded information in the received signal into its original form. In addition to the desired signal, the received signal consists of possible jamming interference and noise [10]. Figure 2.7 offers a functional block diagram of a Direct Sequence Spread Spectrum receiver. Assuming synchronization at the receiver, the received signal is multiplied by a locally generated replica of the PN sequence and demodulated with the local carrier. The resulting signal is

**Figure 2.7. Simplified DS-SS Receiver:  $K = 1$  User [from [8]]**

integrated over a one-bit duration  $T_b$  followed by a decision block. The receiver repeats this multiplication of the received signal with each known PN sequence. Thus, it can differentiate  $N_p$  different signals. The resulting receiver can be envisioned as a bank of correlators. Figure 2.8 depicts  $N_p$  crosscorrelations of the received signal.

**Figure 2.8. Simplified DS-SS Receiver: Bank of Correlators [from [8]]**

#### **D. MODELING THE CHANNEL**

Multiple paths, signal fading, shadowing, reflections, and propagation loss are unique concerns in the radio environment [8,13]. Path losses in radio channels have been studied extensively and several models are proposed in the literature [8]. This thesis implements the 2-ray model as defined in [8]. The defined received power is

$$P_r = P_t G_t G_r \frac{h_t^2 h_r^2}{d^4} \quad (2.10)$$

where  $P_t$  is the transmitted power,  $G_t$  and  $G_r$  are the respective transmitter and receiver antenna gains,  $h_t$  is the transmitter antenna height,  $h_r$  is the receiver antenna height, and  $d$  is the separating distance (meters) of the transmitter-receiver pair. For large values of  $d$ , the received power and path loss become independent of frequency in the 2-ray model [8]. Large distances are considered valid where  $d \gg \sqrt{h_t h_r}$ . For the system being considered, we have the following typical values:  $d = 5$  km,  $h_t \leq 20$  meters, and  $h_r \leq 2$  meters, hence the 2-ray model is considered valid for this implementation.

The bit error rate (BER) is one of the most critical components of channel characterization. The BER may be a function of several parameters, depending on the

channel model used. Multipath and fading are major contributors to the radio channel bit error rate. The probability of error in a Rayleigh fading channel (coherent BPSK) is given as [14]

$$P_e = \frac{1}{2} \left( 1 - \sqrt{\frac{\overline{\gamma_b}}{1 + \overline{\gamma_b}}} \right) \quad (2.11)$$

where

$$\overline{\gamma_b} = \frac{E_b}{N_0} E(\alpha^2).$$

$E(\alpha^2)$  is the average value of  $\alpha^2$ , the attenuation factor, and

$$\frac{E_b}{N_0} = SNR - 10 \log_{10}(R_b). \quad (2.12)$$

The standard Gaussian approximation (SGA) in [15] is often used in determining the bit error probability in CDMA systems [8,16]. For a non-fading, noise-limited channel with perfect power control, the average probability of bit error is given as [8]

$$P_e = Q \left( \sqrt{\frac{1}{\frac{K-1}{3k} + \frac{N_0}{2E_b}}} \right) \quad (2.13)$$

where  $K$  is the number of multiple users and  $k$  is the number of chips per information bit assuming short code implementation.

This thesis incorporates BER modeling for both a Rayleigh slow fading channel and a noise limited channel without fading. The BER calculations are based on Equations (2.11) and (2.13), respectively.

## E. SUMMARY

This chapter reviewed the modeled system as single cell consisting of a base station and  $K$  nodes. We briefly reviewed the traffic models that will be employed and medium access control and CDMA techniques as they pertain to this model. The

propagation model and BER models for channel characterization were given. The next three chapters detail the implementation aspects of medium access control, CDMA , and the radio channel using the OPNET modeling software.

### III. MODELING THE TRANSMITTER

The goal of this and the following chapters is to detail the OPNET implementation of the proposed system. This chapter addresses the implementation issues of the transmitter. The transmitter can be divided into three functional areas: traffic generation, access control to the radio channel, and the physical interface of the transmission. Figure 3.1 offers a graphical view of the transmitter model, consisting of three user defined processes and the OPNET supplied radio transmitter and antenna modules. The objective of this chapter is to model each functional block.

**Figure 3.1. Transmitter Node Model**

#### A. TRAFFIC GENERATION

This section reviews the traffic models and their packet formats. Three different traffic models are employed. The voice and data models outlined in [6] were modified as necessary for this effort. A third traffic model generating a constant rate of traffic is added.

##### 1. Upper Layer Packet Format

As this effort is focused on the lower layers of the communications system, arriving packets are considered a single entity. Any required packet segmentation is assumed to have occurred prior to the packet's arrival. The lower layers' addressing and other responsibilities are not implemented.

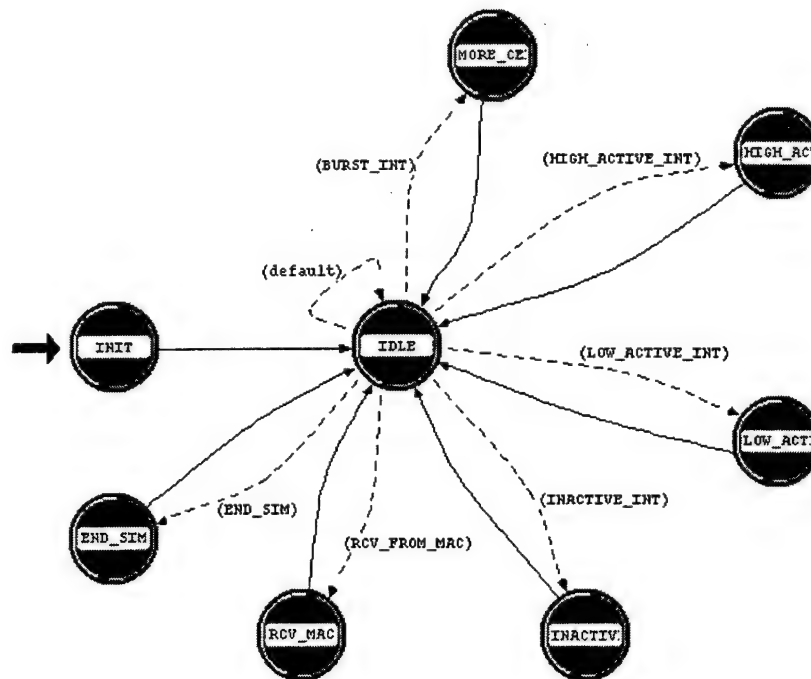

The packet format for all three traffic models is the same. Regardless of the traffic source, the packet generated is formatted as shown in Figure 3.2.

**Figure 3.2. Upper Layer Packet Format**

## 2. Data and Voice Traffic

The data traffic generation process consists of the states depicted in Figure 3.3. The model generates traffic at an average rate of 3.85 packets per second for each of  $N_D$  data sources, where  $N_D$  is user definable [6].

**Figure 3.3. State Transition Diagram of Data/Voice Traffic Generation Process[from [6]]**

The voice model is graphically quite similar to the data model shown in Figure 3.3, differing in that it models a two way conversation and offers a higher rate of traffic. Whereas the data model generates traffic for  $N_D$  sources, the voice model generates traffic for  $N_S$  two-way speech conversations at an average rate of 75 packets per second per conversation.

### 3. Constant Rate Traffic

The constant rate traffic generator depicted in Figure 3.4 is functionally quite similar to OPNET's ideal source generator. It differs in that it generates and transmits packets of the format shown in Figure 3.2 at a constant rate.

Figure 3.4. State Transition Diagram of Constant Rate Traffic Generation Process

### 4. Init State

The activity performed in the INIT state (Figures 3.3 and 3.4) is common to all three traffic models. Within the INIT state, the two user definable simulation parameters listed in Table 3.1 are queried for and obtained. The *Active Sources* parameter determines the number  $N_D$  of data or  $N_S$  of voice sources the model will generate, respectively. For example, with  $N_D = 10$ , the data model of [6] shown in Figure 3.3 will produce 10 separate data sources, each generating an average of 3.85 packets/sec. *User Data Bits* is

the user's choice for a data bit stream (0001110...). This bit stream is repeated over the length of the packet to set the bits of each packet and represents the information data bits received from the higher layers.

**Table 3.1. Traffic Generator Simulation Parameters**

<b>Simulation Parameter</b>	<b>Data Format</b>
<i>Active Sources</i>	Integer
<i>User Data Bits</i>	Character String

## **B. MEDIUM ACCESS CONTROL**

The reader might consider medium access control similar to access control of a busy freeway. Consider the RF radio channel medium as the freeway. In simplistic terms, this is the functionality of the MAC layer. In this section, we offer the models' implementation.

### **1. MAC Layer Packet Format**

We first consider the formatting of the packet performed at this level. Figure 3.5 depicts the MAC layer packet format. A MAC header is provided, but the addressing and other information normally present in the header is not implemented. The MAC header for this model consists simply of all 1s.

**Figure 3.5. MAC Layer Packet Format**

### **2. Slotted ALOHA Implementation**

In this section we discuss the INIT, IDLE, QUEUING, and TRANSMIT states of the slotted ALOHA process shown in Figure 3.6. The functions of this process consist of

enqueueing received information packets and transmitting them to the physical layer at the appropriate slot time. Prior to transmitting them, however, the MAC header is added to the information packet to create the MAC layer packet format shown in Figure 3.5.

Figure 3.6. State Transition Diagram of the Slotted ALOHA Process

*a. Init State*

Within the INIT state variables are initialized and the user definable simulation parameters shown in Table 3.2 are queried and obtained. *Slot length* allows the

Table 3.2. Slotted ALOHA Process Simulation Parameters

Simulation Parameter	Data Format
<i>Slot Length</i>	Double
<i>Chip Rate</i>	Double
<i>Guard Band</i>	Integer

user to define a slot length of the their choice. If the user accepts the models' default implementation, we determine slot length (seconds) as

$$T_s = \frac{L_P}{R_c} \quad (3.1)$$

where  $L_P$  is the packet length (bits) and  $R_c$  is the chip rate of the transmitter (bps for this notation; at this level, bits/chips are synonymous). Note that  $L_P$  is not the MAC packet length in bits, rather the bit length of the packet which will be transmitted from the physical layer transmitter. Although this packet is not actually dealt with until the next section, it is important at this point to consider the spread packet that is actually transmitted.

The actual packet format which will reach the physical layer was shown in Figure 3.5. This model implements limited synchronization functionality by prefacing the MAC packet with a physical layer synchronization frame. A notional guard band frame is added as a trailer. Figure 3.7 depicts the notional physical layer packet format. Before actually being transmitted, this packet will be spread by the transmitter's PN code.

**Figure 3.7. MAC View of the Physical Layer Packet Format**

This spread packet has length  $L_P$  which the MAC process must account for in determining the slot length. Accounting for this spreading then,

$$L_P = (\text{Sync Bits} + \text{MAC Header} + \text{Information} + \text{Guard Band}) \times G_{DS} . \quad (3.2)$$

The actions performed within the INIT state are accomplished at the beginning of the simulation, effectively at time  $t = 0$ . Upon completion, the process is forced to the IDLE state to await a condition invoking a transition to another state. The choices are the QUEUING or TRANSMIT state.

#### ***b. Queuing and Transmit States***

Transition to the QUEUING state is invoked upon receiving a packet from the upper layer. In OPNET terms, the simulation kernel (SK) delivers an interrupt

indicating a packet arrival. Within the QUEUING state the received packet is enqueued and the process returns to the IDLE state. At every slot time  $T_s$  a transition is made to the TRANSMIT state. If the queue has packets, one is retrieved, a MAC header is added to create the packet format shown in Figure 3.5, and the packet is sent to the physical layer. The process then immediately returns to the IDLE state to await either another packet arrival or another slot time.

## C. SPREAD SPECTRUM

### 1. Physical Layer Packet Format

The task of the physical layer is to transmit the packet received from the MAC layer to the channel. The packet is normally prefaced with physical layer information consisting minimally of a synchronization frame [9]. Chapter V discusses the specifics of OPNET in that the SK provides implicit synchronization. Synchronization in a spread spectrum system is beyond the scope of the work reported here. We note its requirement by including nominal synchronization functionality.

The physical layer packet format shown in Figure 3.7 has a notional guard band attached. The packet format without the guardband is shown in Figure 3.8.

**Figure 3.8. Physical Layer Packet Format**

The synchronization frame is defined similar to the MAC header, consisting of all 1s. Prior to transmission, the complete packet is spread with the PN sequence assigned to this transmitter.

### 2. Spread Spectrum Implementation

In this section we discuss the process of implementing spread spectrum. The process consists of the INIT, IDLE, and SPREADING states shown in Figure 3.9.

**Figure 3.9. State Transition Diagram of the Spreader Process**

**a. INIT State**

Within the INIT state variables are initialized and the user defined simulation parameters listed in Table 3.3 are queried and obtained. *User Register Load* defines the initial condition of the shift register used in generating the transmitter's PN sequence. *Polynomial* is the characteristic polynomial defining the feedback taps of the shift register as discussed in section 2.C. Implied is the static allocation of the transmitter's PN code. It is determined at initialization based on *Polynomial*.

**Table 3.3. Spreader Process Simulation Parameters**

Simulation Parameter	Data Format
<i>User Register Load</i>	Character String
<i>Polynomial</i>	Character String

Dynamic assignment or allocation of PN codes is not implemented. The PN code generated for the transmitter is determined within this state and maintained for persistence. It is used repeatedly by the TRANSMIT state for the actual spreading of the packet.

**b. IDLE State**

Upon completing initialization, the process is forced into the IDLE state where it awaits traffic from the upper MAC layer. Transition from IDLE is conditioned on MAC\_ARRIVAL, defined as receiving a packet from the MAC layer. This event

indicates the slotted ALOHA process has reached a slot time and has transmitted an enqueued packet to the physical layer for transmission.

*c. Spreading State*

This state implements the physical transmission of the MAC packets. After obtaining the incoming packet, synchronization bits are prefaced on the packet and the combined packet is spread with the PN code.

At this point the packet consists of a sequential string of 1s and 0s without discernible boundaries. This bitstream is encoded as a sequence of 1s and -1s. Figure 3.8 offers a representative view. The actual mapping is irrelevant; it is only necessary that the receiver is consistent and knowledgeable of the encoding scheme. As defined in Chapter II, an information bit 1 is spread with the PN sequence. An information bit 0 is spread with the inverse of the PN sequence. The spread 0s are encoded as -1s and the spread 1s are encoded as +1s.

**D. THE RADIO TRANSMITTER MODULE**

OPNET provides a built-in radio transmitter module, requiring only that the user properly define the values for the attributes listed in Table 3.4.

**Table 3.4. Radio Transmitter Attributes**

ATTRIBUTE	VALUE
Name	User's Choice
Channel	(...)
Modulation	BPSK, QPSK, DPSK, ...
RX Group Model	User's RX Group Model
TX Delay Model	User's TX Delay Model
Closure Model	User's Closure Model
Channel Match Model	User's Channel Match Model
TX Antenna Gain Model	Isotropic or User's model
Propagation Delay Model	User's Propagation Delay Model
Icon Name	User's Choice

The values of the various *Model* attributes are user defined files known as pipeline stages. The requirements are the proper naming of the C source code file that implements the respective pipeline stage. The pipeline stages are the implementation of the RF channel, and in effect, provide the link analysis. Chapter IV is devoted to channel characterization and provides the details of each stage.

*Modulation* is used internally by OPNET to determine the bit error rate. It is based on OPNET's internally defined bit error rate tables. We will see in Chapter IV where we provide this model's implementation of bit errors. Thus, this parameter is not applicable to this model.

The *channel* attribute listed in Table 3.4 is further characterized by the parameters listed in Table 3.5.  $C_i$  represents the respective channel of which there may be several.

**Table 3.5. Transmitter Channel Parameters**

$C_i$	<i>Data Rate</i>	<i>Packet Format</i>	<i>Bandwidth (kHz)</i>	<i>Minimum Frequency (MHz)</i>	<i>Spreading Code</i>	<i>Transmitted Power</i>
-------	------------------	----------------------	------------------------	--------------------------------	-----------------------	--------------------------

The *data rate* parameter is typically the information data rate. This parameter is queried in the pipeline stages and used, for instance, in the transmit delay stage to determine the time delay for transmitting the packets. It is in reality the chip rate.

The *packet format* parameter defines the particular packet format utilized on this channel. This parameter can be all inclusive to accept packets of any format and/or nonformatted packets, or can selectively allow access to the channel for only defined formats. The *bandwidth*, *minimum frequency*, *spreading code*, and *transmitted power* are self explanatory user definable parameters. The *spreading code* parameter is of limited use in this model. This parameter accepts either a Boolean value or an integer. It does not provide the functionality needed for evaluating PN codes on a bit basis. It is disabled in all transmitter channels.

## **E. THE TRANSMITTER ANTENNA MODULE**

OPNET also provides the antenna module. The module permits modeling of directional or isotropic antennas. Interested reader may refer to the OPNET manuals [17]

for a detailed discussion on modeling directional antennas. This model employs isotropic transmitting antennas.

## **F. SUMMARY**

This chapter detailed the implementation of the transmitter. We have followed the packet flow from generation through the physical spreading. The original information packet now has an additional MAC header and synchronization frame, and this complete packet has been spread with the transmitter's PN code. The packet is now destined for a receiver, but it will first need to traverse the RF channel. The packet undergoes modifications and suffers loss in the form of bit errors as it traverses the channel. The next chapter details the model's channel characterization.

## IV. MODELING THE CHANNEL

Channel characterization is a key component of any radio communications model and there are several critical issues to evaluate. This chapter addresses the implementation of these issues. Modeling radio channels within OPNET requires the 14 pipeline stages shown in Figure 4.1. The objective of this chapter is to model the RF channel utilizing these stages. This chapter presents the implementation of each stage with particular focus on the Interference, SNR, BER, and Error Allocation stages.

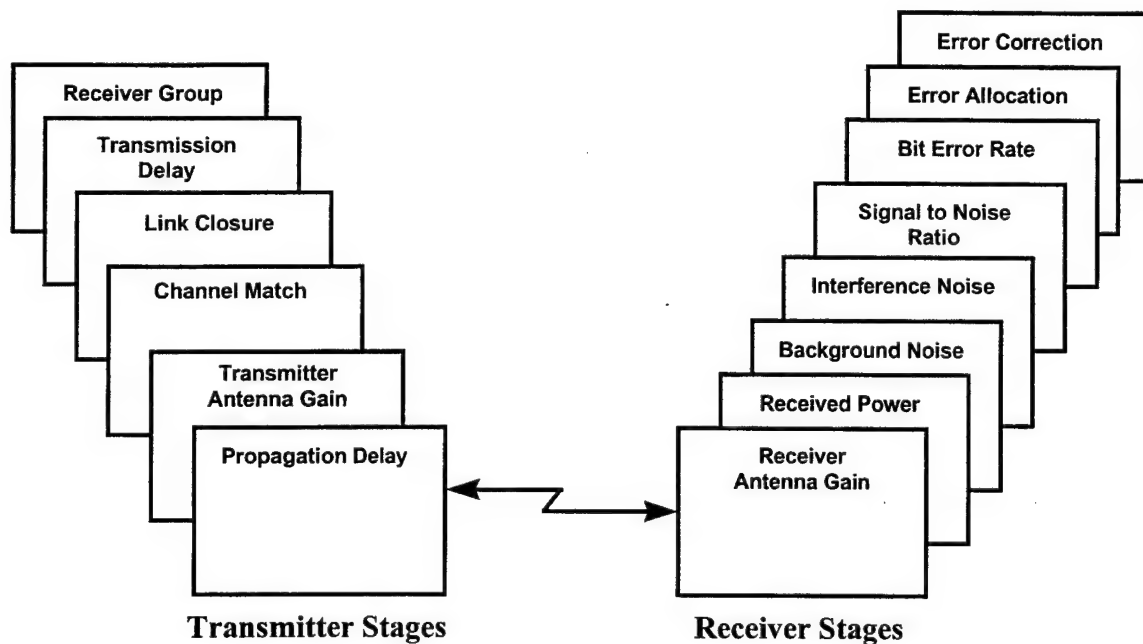

Figure 4.1. OPNET's Radio Channel Pipeline Stages

### A. TRANSMITTER STAGES

#### 1. Receiver Group

The receiver group stage is not part of the dynamically executed stages of the remainder of the pipeline. It is executed only once at the beginning of the simulation. As radio transmissions are initiated, OPNET's simulation kernel (SK) establishes a destination channel set between all known transmitters and receivers in the system. For each receiver the transmitter maintains a separate channel set; together all the channel sets

make up a destination list. During transmission (simulation), the pipeline stages will be executed for each channel set in this destination list. In this receiver group stage, the designer has the opportunity to exclude a receiver from a transmitter's destination list. By default, OPNET does not exclude any receivers in the network and allows the pipeline stages to dynamically make the determination. We employ the default for the receiver group stage.

## 2. Transmission Delay

This stage determines the time delay for transmitting the packet. The delay is computed as the packet bit length,  $L_p$ , divided by the channel data rate,  $R_c$ :

$$tx_{delay} = \frac{L_p}{R_c} . \quad (4.1)$$

Note that  $R_c$  is the channel attribute *data rate* discussed in section 3.D. The delay value obtained is placed in the appropriate Transmission Data Attribute (TDA) of the respective packet.

## 3. Link Closure

The link closure stage determines if a particular receiver can be affected by a transmission. The functionality of this stage is similar to the receiver group stage, but it is executed dynamically with every packet. Link closure is determined based on the line-of-sight propagation path assumption between the transmitter and the receiver. By default, OPNET utilizes a ray-tracing line-of-sight algorithm with the earth's surface modeled as a sphere [17]. The Boolean value indicating link closure is placed in the appropriate packet TDA. This model implements the OPNET default pipeline stage.

## 4. Channel Match

The channel match stage classifies transmitted packets as one of three categories; **valid**, **noise**, or **ignored**, with respect to a particular receiver. **Ignored** packets are not further evaluated by the remaining stages.

Channel match is a function of *frequency*, *bandwidth*, *data rate*, *spreading code*, and *modulation type* of both the transmitter and receiver. These are user definable parameters discussed in section 3.D. Packets with non-overlapping *frequencies* between

the transmitter-receiver (tx-rx) pair are classified as **ignored**. Packets with one or more mismatched parameters are classified as **noise**. Packets whose set of tx-rx parameters are completely matched are **valid**.

As the *spreading code* attribute is disabled in all transmitters and receivers, this assures no link will be classified based on the PN code within this stage. Chapter V will discuss how we determine a PN code match or mismatch in the receiver.

## 5. Transmitter Antenna Gain

This stage determines the gain of the transmitting antenna. The proposed system is modeled using isotropic transmitter and receiver antennas, which is simplistic in terms of necessary calculations. The uniform gain (0 dB) of the transmitting antenna is set in the appropriate packet TDA during the execution of this stage.

## 6. Propagation Delay

The propagation delay stage is the final pipeline stage associated with the transmitter. The propagation delay determines the time lapse between the transmission of the first bit of a packet at the transmitter and the arrival of the first bit at the receiver. As either transmitter or receiver may be mobile, two calculations are performed. The first calculation accounts for the distance separating the tx-rx pair at the beginning of packet transmission, and the second for the distance separating the tx-rx pair at the end of packet transmission. The propagation delays are calculated as

$$t_{prop} = \frac{d_i}{C} \quad (4.2)$$

where  $d_i$  is the respective start/end transmission distance, and  $C$  is the velocity of radio wave propagation.

## B. RECEIVER STAGES

The remaining stages are associated with the receiver. In these stages the model differs from OPNET's default pipeline stages. A thorough understanding of the detailed workings of the OPNET software is critical to correctly model this system. Of critical importance are the Interference Noise, the SNR, and the BER stages. Appendix B

provides a detailed discussion of the model's implementation of these three pipeline stages.

### 1. Receiver Antenna Gain

This stage follows in concert with the transmitter. Similar to the transmitting antennas, the receiver antenna is modeled as isotropic. A uniform gain (0 dB) is set in the appropriate TDA.

### 2. Receiver Power

This stage determines the received power level of the incoming packet. It is calculated in accordance with Equation (2.9) and set in the packet's TDA.

### 3. Background Noise

The background noise stage models noise sources other than interference noise sources introduced by other transmitters or other intentional interfering sources. The major noise contribution is due to the thermal noise power:

$$N_B = kT_S B \text{ (Watts)} \quad (4.3)$$

where  $k$  is Boltzmann's constant,  $T_S = T_R + T_0$ , and  $B$  is the effective *bandwidth* of the receiver. *Bandwidth* is the user definable channel attribute (see section 3.D). The effective receiver temperature  $T_R$  is determined as

$$T_R = (F - 1)T_0 \quad ^\circ\text{K} \quad (4.4)$$

where  $F$  is the receiver *noise figure* and  $T_0$  is the background source temperature, taken to be 290 °K. The receiver *noise figure* is a user definable attribute. The default model includes a negligible contribution of ambient noise. As this ambient noise is negligible, it is neglected in this model. The determined noise contribution  $N_B$  is set in the appropriate packet TDA.

#### 4. Interference Noise

This stage accounts for noise interference that packets may impose upon each other. In effect, it accounts for multiple access interference (MAI). This stage is invoked from the SK only in the case of overlapping packet reception and only at the beginning of packet reception.

The interference power,  $N_i$ , on the respective packet segment is determined by

$$N_i = \sum_{i=1}^M P_i \quad (4.5)$$

where  $M$  is the instantaneous number of interfering packets (multiple users), and  $P_i$  is the received power of the respective packet. In this implementation, all transmitters transmit equal power and are equidistant from the receiver, thus  $N_i = MP_r$ , where  $P_r$  is given in Equation (2.9).

#### 5. Signal-to-Noise Ratio

This stage determines the SNR on a packet segment based on the background noise during the segment interval. The interfering and background noise are determined in the previous two stages. The background noise is constant over the length of the packet. In the case of packets of different lengths,  $N_i$  may vary over the length of the packet with a corresponding variation in the SNR. By default, OPNET determines the SNR as

$$SNR \text{ (dB)} = 10 \log_{10} \left( \frac{P_r}{N_i + N_B} \right) \quad (4.6)$$

where  $P_r$  is the received power,  $N_i$  and  $N_B$  are the interference and the background noise, respectively.

In the Bit Error stage, the multi-user interference is accounted for in the bit error calculation. The SNR pipeline stage is thus modified and the resultant SNR is only due to the signal to thermal noise ratio, defined as

$$SNR \text{ (dB)} = 10 \log_{10} \left( \frac{P_r}{N_B} \right). \quad (4.7)$$

## 6. Bit Error Rate

This stage determines the packet segment BER. For packets of equal length, the BER is constant over the length of the packet. Otherwise, it will vary in accordance with the SNR. Here we implement two BER models. For modeling fading channels, the BER is determined by Equation (2.12). Non-fading channels are modeled by Equation (2.14). In this stage, we account for the interfering users whose contribution was omitted in the SNR stage. The calculated BER is set in the packet's TDA.

## 7. Error Allocation

This stage is executed immediately after the BER pipeline stage completes execution. In this stage, we inject errors in the packet at the bit error rate determined by the BER stage. This stage determines the packet segment length defined in the BER stage, and sequences over this segment of the packet randomly inverting bits within the packet at a rate equal to the BER. As the bits are encoded as +1s and -1s, selected +1s are set to -1, selected -1s become +1.

This model employs packets of equal length. Thus, the packet segment length is equal to the packet length,  $L_p$ . The approach to injecting errors can be shown with the following pseudocode.

```
for(i = 0; i <  $L_p$ ; i++)  
{  
    random_number = rand(0,1);  
    if(random_number ≤ BER)  
        invert_packet_bit(i);  
}
```

where `invert_packet_bit()` indicates changing the sign of the respective bit as noted in the previous paragraph.

## 8. Error Correction

This stage determines the acceptability of the packet. This determination is based upon two criteria: the availability of the receiver and the bit error rate of the packet.

Should the receiver become disabled during packet reception, the respective packet is rejected and the SK automatically destroys the packet. If the rate of actual errors injected in the Error Allocation stage exceeds the *error correcting threshold*, the packet is rejected; again, the SK automatically destroys the packet. The *error correcting threshold* is a receiver channel attribute to be discussed in Chapter V.

### C. SUMMARY

This chapter encompasses the second of the three modules of this model. Presented was the implementation of the RF channel characterization. The first section reviewed the pipeline stages associated with the transmitter. The second reviewed the stages associated with the receiver, where we reviewed the model's implementation of determining the BER and injecting the bit errors accordingly. The original information has thus undergone several changes: a MAC header and a synchronization frame are added, the bits have been spread, and errors have been injected into the packet. The final implementation aspect of this model is to determine if the packet is recoverable and the original information retrievable. Chapter V details the receiver implementation.

## V. MODELING THE RECEIVER

This chapter presents the receiver implementation of the model. The objectives of this chapter are to properly model limited synchronization, code division multiple access, and signal despreading in a spread spectrum system. Figure 5.1 offers a graphical view of the receiver model. This chapter focuses on the functions of the despreader and details the OPNET implementation of this spread spectrum receiver.

**Figure 5.1. OPNET Receiver Node**

### A. THE RECEIVER ANTENNA MODULE

Similar to the transmitter, the receiver employs the OPNET isotropic antenna module.

### B. THE RADIO RECEIVER MODULE

OPNET provides a built-in radio receiver module, requiring only that the user properly define the values for the attributes listed in Table 5.1. The values for the various *Model* attributes are the user defined receiver pipeline stages discussed in Chapter IV. The requirements are the naming of the C source code files which implements the respective pipeline stage.

The value of *Noise Figure* is queried for in the Background Noise pipeline stage and is necessary to determine the receiver temperature,  $T_R$ , in Equation (4.4). *ECC Threshold* is the percentage of errors per packet that the receiver will accept; it is queried for in the Error Correction pipeline stage.

**Table 5.1. Receiver Module Attributes**

ATTRIBUTE	VALUE
Name	User's Choice
Channel	(...)
Modulation	BPSK,QPSK,DPSK, ...
Noise Figure	User Defined
ECC Threshold	User Defined
RX Antenna Gain Model	Isotropic or User's model
Power Model	User's Power Model
Background Noise Model	User's BNoise Model
Interference Noise Model	User's INoise Model
SNR Model	User's SNR Model
BER Model	User's BER Model
Error Model	User's Error Model
ECC Model	User's ECC Model
Icon Name	User's Choice

The receiver *Channel* attribute is further characterized by the parameters listed in Table 5.2. These parameters are identical to those in the transmitter with the exception of *processing gain* (see section 2.C.1.b).

**Table 5.2. Receiver Channel Parameters**

$C_i$	<i>Data Rate</i>	<i>Packet Format</i>	<i>Bandwidth (kHz)</i>	<i>Minimum Frequency (MHz)</i>	<i>Spreading Code</i>	<b><i>Processing Gain</i></b>
-------	----------------------	--------------------------	----------------------------	--	---------------------------	-----------------------------------

## C. CONFIGURING THE RECEIVER

This section reviews the configuration of the modeled receiver. A spread spectrum receiver is capable of receiving multiple packets simultaneously. To successfully receive

multiple packets, the receiver must first be able to synchronize with the arriving packet(s). This model implements limited synchronization, which we define as successfully decoding the synchronization frame of the arriving packets. In order to decode the synchronization frame, the receiver must first despread the arriving packet's synchronization frame. Despreading is accomplished by crosscorrelating the arriving packet's synchronization frame with PN codes generated within the receiver. The receiver needs multiple PN codes with which it can attempt to despread the arriving packet. In configuring the receiver, we generate these multiple PN codes initially.

The complete despreading process consists of the INIT, IDLE, SYNC and DECODE states shown in Figure 5.2. A detailed discussion of each state is presented below.

**Figure 5.2. State Transition Diagram of the Despreader Process**

### 1. INIT State

Within the INIT state, variables are initialized and the simulation parameters shown in Table 5.3 are queried and obtained. *Synchronization threshold* and *data threshold* are thresholds which must be reached to successfully achieve synchronization and decode the information bits, respectively.

**Table 5.3. Despreader Process Simulation Parameters**

Simulation Parameter	Data Format
<i>Synchronization Threshold</i>	Double
<i>Data Threshold</i>	Double
<i>Long Correlation</i>	Boolean

The parameter *long correlation* has a significant impact on simulation performance. It determines the number of crosscorrelations the receiver will perform in the attempt to synchronize with arriving packets. As the receiver is designed to receive and despread  $\leq N_p$  PN codes, these codes must be known to the receiver. For each code, there are  $k$  possible IC's (see Chapter II) of the shift register and  $k$  chips per code. Thus, the receiver must be configured with  $N_p k^2$  codes which it can utilize to crosscorrelate with the arriving packet(s). These codes are all generated in the INIT state and retained. Figure 5.3 offers a logical view of this persistent matrix of PN codes. IC<sub>1</sub> for generating each  $PN_i$  code indicates the initial condition of the shift register was set with the least significant bit as 1 (0x1), and all other bits set to 0. The remaining (up to  $k$ ) codes are generated with the other initial conditions of the shift register. For example, the code for each IC<sub>2</sub> was generated with an initial condition of the shift register set to 2 (0x2).

**Figure 5.3. Receiver PN Code Matrix**

In the SYNC state, the arriving packet is crosscorrelated with the codes of this matrix in an attempt to achieve synchronization. *Long correlation* determines if the model will execute  $\leq N_p k^2$  crosscorrelations as necessary, or only  $PN_{i,IC_1}$ ,  $i = 1..N_p$  of

them. With *long correlation* disabled, a transmitter's code generated with an IC other than 0x1 should not achieve synchronization. Bit errors could prove this false. With *long correlation* enabled, the user has flexibility. The price is increased simulation time. By default, *long correlation* is disabled. The user determines the IC of the transmitter's shift register with the *User Register Load* parameter (see Chapter III).

Upon completion of the INIT state, the process is forced to the IDLE state, where it awaits incoming packets. Upon a packet's arrival, the first objective is achieving synchronization.

#### **D. SYNC STATE**

This model implements limited synchronization functionality. As OPNET is a discrete time, event driven modeling system, true modeling of spread spectrum synchronization would be prohibitive in terms of simulation time. Slotted ALOHA ensures transmitted packets arrive simultaneously. Packet synchronization is achieved as OPNET delivers the complete packet to the receiver, i.e., the receiver is not constantly sampling a received signal attempting to synchronize on a bit stream.

A realistic modeling of this receiver would require parsing the packet bit by bit and correlating first one, then two, then three and on until the time we had received the complete packet. Synchronization is a complex issue. There is phase synchronization, frequency synchronization, chip synchronization, code synchronization and others to be concerned with [14]. As OPNET delivers the complete packet to the receiver via a stream interrupt, we assume that synchronization is achieved, and the treatment of synchronization here is limited to recovering the PN code.

##### **1. Determining Synchronization**

We transition to the SYNC state on the condition PKT\_RECEIVED, indicating one or more packet arrivals. From the matrix of codes generated in the INIT state, we can precisely outline the implementation of this state with pseudocode. The simplified version is as offered below. With *long correlation* disabled, *j* is fixed at 1, such that only the first sequence of each PN code will be used in the crosscorrelation process with the arriving packet:

```

Do{
  for(i ≤ Np)
    for(j < k)
      sync = xcorr(PNi,j, packet)
    end
  end
}while(sync threshold not met && more codes to check)

```

Achieving synchronization of a packet is the first step in considering the packet as successfully received. Packets that cannot be synchronized are considered lost packets and they are destroyed.

## 2. Multiple Access Reception

The proposed system must incorporate multiple simultaneous reception of packets. The second step in deciding successful packet reception is to determine if all simultaneously received synchronized packets have unique PN codes. Packets containing duplicate PN codes are considered collisions and destroyed.

Consider the simultaneous reception of three packets. The receiver chooses one of the packets. Assuming the receiver is able to synchronize on the first packet, we must ensure that we maintain this packet. It is a **candidate** for a successfully received packet. We cannot, however, consider it a valid received packet until all three have been synchronized and determined to have unique PN codes. If all three do contain unique PN codes, then, and only then, can we consider the three as successfully received packets.

Internally, OPNET maintains an event list comprised of events scheduled for various simulation times. The event list contains at least three events scheduled for time  $t = now$ ; the arrival events of the three packets. We do not transition to the DECODE state until we have processed all *packet arrival* events scheduled for time  $t = now$ .

The model maintains each synchronized packet in a list schematically shown in Figure 5.4. A separate list is maintained for each defined PN code. If synchronization is achieved on an arriving packet, the packet is inserted in this list for persistence. Should two packets synchronize on PN<sub>2</sub>, both packets will be inserted into the same list. For example, the list pointed to by the PN<sub>2</sub> list pointer will have two packets in this list, as shown in the diagram. Additionally, an OPNET interrupt labeled SYNC\_ACHIEVED is scheduled to occur at time  $t = now + \tau$ . After all simultaneously arriving packets have

been evaluated, this process returns to the IDLE state. A SYNC\_ACHIEVED interrupt will cause a transition to the DECODE state,  $\tau$  seconds later.

**Figure 5.4. Persistent List of Synchronized Packets**

### 3. Decoding Delay

The parameter  $\tau$  referred to in the SYNC state is an induced time delay which prevents the process from transitioning directly from the SYNC state to the DECODE state. The purpose of  $\tau$  is twofold. First, to provide a time gap separating the events of SYNC and DECODE. Second, to accommodate any internal variance of times maintained by OPNET for the start of reception of other packets.

The value of  $\tau$  must be nominal such that packets from later slot(s) are not included in the list of synchronized packets, i.e., the current set of simultaneously arriving packets must be decoded before the next time slot. Equidistant transmitters and the MAC ensure simultaneous arrival. For transmitters at varying distances, we assume receiver feedback to ensure that all packets arrive at the beginning of a slot time.

### E. DECODE STATE

This state determines packet collisions, despreads non-colliding packets, and attempts recovery of the original information. Transition to this state is conditioned on ACHIEVED\_SYNC, defined as 1) synchronization achieved and 2) invocation of a SYNC\_ACHIEVED interrupt.

### 1. Collision Decision

Packet collision is determined by evaluating the list(s) indicated in Figure 5.4. Any list(s) of  $PN_i$  maintaining  $J > 1$  packets indicates duplicate codes. All  $J$  packets are destroyed.

### 2. Strip, Despread, Decode

For all  $PN_i$  maintaining  $J = 1$  packet, the packet is considered as received successfully. Now, the receiver can move ahead to decoding and desreading the packet. Desreading and decoding are accomplished by crosscorrelating the spread information bits with the respective PN code(s) recovered in the SYNC state. A single iteration through the list in Figure 5.4 will identify all successfully received packets which can now be decoded.

Decoding results in either a recovered 1 or 0 as appropriate, or this model flags information bit errors as -1 for bits failing to reach correlation exceeding *data threshold*. Table 5.4 depicts the trivial case of  $n = 3$ ,  $k = 7$ , indicating the original information bits were spread with a PN sequence of seven chips. Information bit 1 consists of the seven encoded bits shown in the first row. Information bit two follows on the second row, and information bit three follows on the third row.

**Table 5.4 Decision value of Recovered Data Bits**

	<b>Spread Bits, PN Code</b>	<b>Normalized Correlation</b>	<b>Data Threshold</b>	<b>Decision</b>
Info Bit 1 PN Code	11-1-11-11 11-1-11-11	1	0.9	0
Info Bit 2 PN Code	-1-111-11-1 11-1-11-11	-1	-0.9	1
Info Bit 3 PN Code	11-1-11-1-1 11-1-11-11	0.71	0.9	-1 (info bit error)

### 3. Event Canceling

The first transition to this state results in destruction of all colliding packets and desreading all successfully received packets. The final actions are traversal of OPNET's event list. All pending interrupt events labeled SYNC\_ACHIEVED scheduled for time

$t = now$  are void, as the synchronized packet which scheduled this interrupt has been processed.

For example, in the case of three simultaneous successful synchronizations, there were three SYNC\_ACHIEVED interrupts scheduled for time  $t = now + \tau$ . Time  $t$  is now equal to  $\tau$ . One of the SYNC\_ACHIEVED interrupts invoked this process. The other two are unnecessary. This model iterates through the event list canceling those unnecessary events.

## **F. SUMMARY**

In this chapter, we presented the details of the modeling a spread spectrum CDMA receiver. Limited modeling of synchronization was presented. We presented in detail the implementation of multiple access mechanisms, using OPNET. The details of despreading and decoding the information bits were also presented.

## VI. SIMULATION RESULTS

In this chapter we present an evaluation of the implemented system by summarizing the simulation results obtained from the model. Both the Rayleigh fading and the standard Gaussian approximation (SGA) bit error rate (BER) models are considered to study the models' channel characterization. We evaluate the multiple access capability of the receiver as a yardstick for the models' CDMA capability and functionality. This evaluation incorporates proper PN code generation, spreading, despreading, decoding and decision making.

The modeled system supports both voice and data users. As shown throughout this writing, a given user may generate more than one call of the respective type ( $N_D, N_S$ ). The number of possible simulations is infinite. Complete verification of all of these aspects would be through intensive testing, simulation and evaluation. Here, we evaluate the networking aspects of this model by testing the system under two typical scenarios: 1) nodes consisting of speech users only, and 2) nodes consisting of data users only.

We demonstrate the performance of the medium access control under the implemented slotted ALOHA MAC and CDMA physical layer. The measurement of performance would be the percentage of spread spectrum utilization of the channel capacity, which we term spread spectrum utilization.

In presenting the models' evaluation, we first offer a common baseline on which the simulations were based. A summary of the simulation parameters used is provided. Next, we present the results of the BER models. The third section offers a graphical presentation of the models' CDMA capability. We conclude this chapter with an evaluation of the performance of the MAC under CDMA.

### A. SIMULATION SETUP

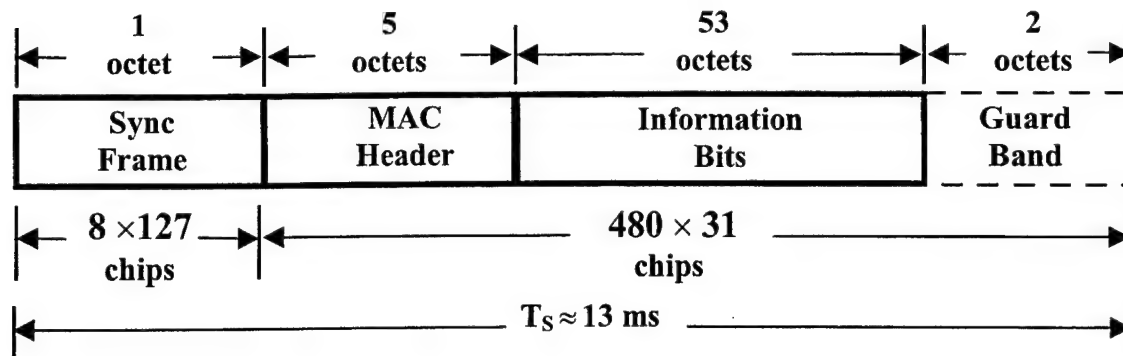

In this section we review the simulation parameters for the model. A partial listing of the user definable parameters is given in Table 6.1. We note unspecified parameters or those that vary from the defaults as necessary.

**Table 6.1. Baseline Simulation Parameters**

<b>Simulation Parameters</b>	<b>Data Format</b>	<b>Default Value</b>
<i>Active Sources</i>	Integer	20 Data / 1 Voice
<i>User Data Bits</i>	Character String	None: User Must Specify
<i>Slot Length</i>	Double	0.0
<i>Chip Rate</i>	Double	1.2288E6 (chips/sec)
<i>Guard Band</i>	Integer	2 (octets)
<i>User Register Load</i>	Character String	None: User Must Specify
<i>Polynomial</i>	Character String	R(3,7)
<i>Sync Threshold</i>	Double	0.8
<i>Data Threshold</i>	Double	0.8
<i>Long Correlation</i>	Boolean	FALSE

As the models of [6] were developed in support of ATM research, here we chose similar packet formats as shown in Figure 6.1. The format consists of a synchronization frame of 1 octet, a 5 octet MAC header, and a 53 octet information packet. The processing gains ( $k$ ) of each segment were 127, 31, and 31 respectively, giving a spread packet length of 15,400 chips. The PN codes were generated with a seven bit register, providing 18 unique PN codes and a processing gain of 127 for the synchronization frame. However, as the traffic models employed have an equivalent data rate of approximately 32 kbps, Equation (2.7) restricts  $k$  to 31. To compensate for this, we reduced the synchronization frame from four octets to one octet. Rather than spreading four octets by 31, we spread 1 octet by 127. This occupies approximately the same bandwidth, yet ensures the sequences generated for spreading the synchronization frame remain orthogonal.

Including guard band time, the resulting slot length,  $T_s$ , of the spread packet is approximately 13 ms. The subchannel capacity is given to be approximately 77 packets per second; the equivalent data rate is approximately 39.6 kbps or 1.228E6 chips per second.

**Figure 6.1. Simulation Packet Format**

The channel is configured with the parameters listed in Table 6.2. As discussed in Chapter III, the *Modulation* parameter is irrelevant in this selection as we determine the BER directly without reliance on OPNETs' internally defined BER tables. However, the user is required to make a choice. The value for *ECC threshold* allows the receiver to accept essentially all packets.

**Table 6.2. Transmitter/Receiver Channel Parameters**

Simulation Parameters	Data Format	Default Value
<i>Modulation</i>	N/A	N/A – Choose Any
<i>ECC Threshold</i>	Double	1 (Accept all errors)
<i>Noise Figure</i>	Double	7 dB
<i>Data Rate (Chip Rate)</i>	Integer	1.2288E6
<i>Bandwidth</i>	Double	2 MHz
<i>Minimum Frequency</i>	Double	824 MHz
<i>Spread Code</i>	Integer	Disabled
<i>Transmitter Power</i>	Character String	Varied

The channel parameters closely resemble those of IS-95; see Table 9-2 of [10]. Shown are 60 subchannels per RF channel which is based on a data rate,  $R_b$ , of 9600 bps, and a chip rate,  $R_c$ , of 1.2288E6 chips per second. As the traffic sources have a data rate of approximately 32 kbps,  $N_p$  is restricted to 12. For the multiple access implementation, the receiver PN code matrix is defined using the following polynomials: R(3,7),

R(2,3,4,7), R(1,2,3,4,5,7), R(1,7), R(6,7), R(1,3,5,7), R(1,2,5,7), R(2,3,4,5,6,7), R(1,2,3,7), R(1,2,4,5,6,7), R(2,4,6,7), and R(1,2,3,5,6,7).

The required channel capacity is

$$C = \frac{N_p}{T_s} \text{ packets per second} \quad (6.1)$$

where  $N_p$  is the number of unique PN codes and  $T_s$  is the slot time in seconds. Thus, the channel capacity for the simulation is

$$C = \frac{12}{0.013} \approx 925 \text{ packets per second.} \quad (6.2)$$

The spread spectrum utilization of the MAC is then given by:

$$\eta = \frac{\text{Successfully Received Packets / seconds}}{C} \quad (6.3)$$

The numerator is calculated by dividing the number of successfully received packets at the receiver by the total simulation time (seconds), where we have defined successfully received packets as those packets that were successfully synchronized and were not considered PN collisions.

## B. BIT ERROR RATE EVALUATION

In evaluating the modeling of the channel, we consider the Rayleigh fading model and the SGA BER as discussed in Chapter II.

### 1. Rayleigh Fading Channel

The results of the Bit Error and Error Allocation pipeline stages implementation of the Rayleigh fading channel BER are shown in Figure 6.2. The curve represents the average rate of errors injected from within the Error Allocation pipeline stage. The curve shows the dependency of the BER on the variation of the received  $E_b / N_0$ . A detailed treatment of fading channels can be found in [10]. The focus here is on the modeling of

such a channel within the OPNET environment. Figure 6.2 illustrates the impact of channel fading and the linear relation between the probability of error and  $E_b/N_0$ . Figure 6.2 shows plots of both the model results and Equation (2.11); however, the results produced by the model match so closely with Equation (2.11), the two curves completely overlap each other. Throughout the simulation, the calculated BER of the Bit Error pipeline stage and the average BER from injected errors within the Error Allocation pipeline stage are quite similar to theoretical expectations.

**Figure 6.2. Rayleigh Fading Channel BER Simulation Results**

## 2. Standard Gaussian Approximation

The implementation results of the SGA model are shown in Figure 6.3. Plotted are the curves for  $K = 3, 6, 9$ , and 12 nodes within the network. The solid curve plots the theoretical BER as determined in the BER pipeline stage. The dashed line curve plots the rate of errors injected into the packets in the Error Allocation pipeline stage. As discussed in Chapter II, this BER modeling is for the case of a non-fading, noise limited channel. The results indicate the BER of injected errors closely parallels the theoretical expectations.

The degradation suffered in a fading channel is apparent when comparing Figures 6.2 and 6.3. This comparison highlights the importance of model selection when

designing a communications system. As the proposed system is essentially a cellular system, the Rayleigh fading model may provide the best realistic expectations.

**Figure 6.3. Model Implementation of Gaussian Approximation**

### C. CODE DIVISION MULTIPLE ACCESS SIMULATION

In this section we evaluate the CDMA capability of the model. The simultaneous reception of multiple packets is illustrated in Figure 6.4. The constant rate traffic source was employed at a rate of 10 packets per second. The upper graph shows the accumulations of the total number of packets transmitted, the total received packets, and the total that were determined as successful receptions. The lower graph magnifies the beginning of the upper graph for clarity. Shown is the case of  $K = 18$ .  $E_b/N_0$  was set to 12 (dBm) such that the probability of synchronization failure was essentially zero, considering Tables 6.1 and 6.2. As shown, 12 of the 18 packets were considered collisions and were rejected.

Figure 6.4. Illustration of Multiple Packet Reception

#### D. EVALUATION OF MAC PROTOCOL PERFORMANCE

Here we discuss the way the MAC performance ( $\eta$ ) is measured and analyze the performance of the slotted ALOHA MAC protocol. We test two cases representing typical scenarios in the military environment: a pure speech network (representing traditional voice networks), and a pure data network (representing new networks for fire control, C<sup>4</sup>I, battlefield dominance, etc.). In each scenario, we analyze the spread spectrum utilization of the protocol under various traffic loads.

## 1. Speech Traffic

The speech model generates traffic at a mean rate of 75 packets/second. Since the subchannel capacity is approximately 77 packets/second, for a single user of a given PN code, the spread spectrum utilization should be approximately 97%.

The simulation results for the pure speech scenario are shown in Figure 6.5. We see that for up to 12 users ( $N_p$ ), the spread spectrum utilization,  $\eta$ , rises almost linearly up to approximately 97%. This is to be expected as all PN codes are unique up to this point and there are no collisions in any of the subchannels. For every additional user beyond  $N_p$ , we see dramatic degradation in  $\eta$  as the subchannels are no longer used by a single user. The high spread spectrum utilization of the subchannel of a single user (approximately 97%) also contributes to the degradation.

Figure 6.5. Spread Spectrum Utilization with Voice Traffic

## 2. Data Traffic

The data model generates traffic at a mean rate of 3.85 packets per second, per data source. The subchannel capacity remains the same as above at approximately 77

packets per second. As each node was simulated with 10 sources per node ( $N_D = 10$ ),  $\eta$  of a single subchannel is expected to be  $\frac{3.85 \times 10}{77}$  or approximately 50%. From Figure 6.6, consider the result for  $K = 12$ . With each node utilizing a unique PN code (thus a separate subchannel) for 50% of the time, we observe that the spread spectrum utilization is slightly less than 50%.

**Figure 6.6. Data Utilization Under Heavy Loads**

Now suppose that traffic from two different nodes is spread equally in time. As each data node multiplexes 10 bursty data streams, we can assume a Poisson behavior for the combined stream [18]. Therefore, the expected spread spectrum utilization for the case of two users per PN code is:

$$\eta^{(2)} = \Pr\{\text{only PN user 1 transmits}\} + \Pr\{\text{only PN user 2 transmits}\}$$

We have shown above that the spread spectrum utilization of each user is approximately 50%. Assuming that the traffic patterns of all users are similar, the spread spectrum utilization,  $\eta$ , given that two PN Codes are used, can be shown to be

$$\begin{aligned}
\eta^{(2)} &= 2 \times \Pr\{\text{only PN user 1 transmits}\} \\
&= 2 \times \Pr\{\text{PN user 1 transmits}\} \times (1 - \Pr\{\text{PN user 2 transmits}\}) \\
&= 2 \times 0.5 \times (1 - 0.5) \\
&= 0.5.
\end{aligned}$$

Figure 6.6 indicates that the measured results compare with the above analysis. For example, for  $K$  equals 24, the spread spectrum utilization is approximately 50%. We can easily extend this analysis to the case of 3 users per PN Code. Based on the above, the spread spectrum utilization can be shown to be

$$\eta^{(3)} = 3 \times 0.5 \times (1 - 0.5)^2 = 37.5\%.$$

From Figure 6.6, for  $K$  equals to 36 nodes, the measured spread spectrum utilization is approximately 37.5%.

#### **E. SUMMARY**

In this chapter we presented simulation results of the implementation of the proposed model in OPNET. BER performance of the RF channel has been studied for both the Rayleigh fading channel and the SGA. Spread spectrum utilization performance of the MAC protocol with an underlying spread spectrum CDMA physical layer was measured.

## VII. CONCLUSIONS AND RECOMMENDATIONS

### A. CONCLUSIONS

The objective of this thesis was the OPNET modeling and implementation of a CDMA system for the uplink transmission of a single cell network. To meet this, we implemented traffic generation, slotted ALOHA medium access control, spread spectrum transmission and (multiple access) reception, and the RF channel processes in OPNET. Also addressed were the issues of packet formatting, time slots within the MAC, packet spreading, bit manipulations of the packets within the BER and Error Allocation pipeline stages, and proper despreading of the packet in the receiver.

The proposed system consists of three major modules: the transmitter, the channel, and the receiver. We implemented all three modules in OPNET. As part of this effort, we were able to use some OPNET supplied modules (with minor modifications), but we developed several other modules as their functionality was not available in OPNET.

As part of the transmitter module implementation, we developed the appropriate traffic generation, slotted ALOHA MAC protocol, PN code generation, and spreading modules. The channel was implemented utilizing OPNET's fourteen stage pipeline architecture. The different pipeline stages had to be appropriately configured to realize two channel models: SGA and Rayleigh fading. The significant effort here consisted of developing the corresponding BER models and injecting errors into packets accordingly.

The receiver implementation consisted of (simplified) synchronization, packet despreading, and packet decoding modules. The functionality of these modules are not readily available in OPNET, hence they were coded and integrated into the model.

The designed system was then simulated, and some performance results were obtained. The bit error rate performance of the system was measured for both SGA and Rayleigh channel models. The measured results agree well with theoretical results. The multiple access performance of the MAC protocol under CDMA was studied by measuring the spread spectrum utilization performance. The measured results were obtained for both voice and data traffic, and they closely match with the expected theoretical performance.

## **B. RECOMMENDATIONS FOR IMPROVEMENTS**

This modeling effort was designed to be a starting point, offering a foundation upon which the proposed communications system might be built. Future work on this model might consider the implementation and evaluation of mixed data and voice traffic, node mobility, power control issues, queuing algorithms, and receiver feedback issues as potential areas of expansion.

Based on the experience of this effort, we conclude that OPNET's modeling software is an excellent tool for wireless network design and simulation. It was a difficult task to understand and utilize OPNET's modeling tools; but once we mastered their basic usage, we found them to be indispensable for any network modeling effort.

## APPENDIX A. AN OVERVIEW OF OPNET

In this appendix we provide a brief overview of the OPNET modeling software package. This appendix reviews the OPNET hierarchy, the concept of OPNET's simulation kernel, the employment of interrupts within an OPNET simulation, and the definition of an OPNET process module. The objective here is to familiarize the reader with the basic workings of OPNET. The reader requiring a more detailed or extensive treatment of OPNET's modeling software package is referred to the 12 volume set of the OPNET user manuals.

### A. THE OPNET HIERARCHY

OPNET is a comprehensive engineering system capable of simulating large communications networks with detailed protocol modeling and performance analysis. OPNET is hierarchical in that it implements models in three levels: the network level, the node level, and the process level. The hierarchy can be envisioned as shown in Figure A.1.

**Figure A.1. OPNET Hierarchical Organization**

At the network level the modeler defines the bounds of the network. The network model may represent a single network or numerous subnetworks. The network model is defined by one of the underlying node models.

The node models are defined by queues, generic processes, traffic generators, transmitters, receivers, antennas and other modules available within OPNET. Figure 5.1 offers a graphical view of the receiver node model implemented in this thesis, and is repeated here as Figure A.2. As shown, it consists of an antenna module, a radio receiver module, and two user defined processes. The PN\_DESPREADER process and the SINK process are two examples of generic processes which the designer has full flexibility in designing. Implementing these generic processes is commonly where the full modeling capability of OPNET is realized.

**Figure A.2. OPNET Receiver Node**

The arrows connecting each module of Figure A.2 play a major role in OPNET. They are referred to as *streams*. The radio\_antenna module has one output stream. The radio\_rcv module and the PN\_DESPREADER process module have one input stream and one output stream. The SINK process module has one input stream. The interconnecting streams are the primary communication link between the different process modules within the node. To understand their use, we review OPNET interrupts and OPNET's simulation kernel.

## **B. INTERRUPTS AND THE SIMULATION KERNEL**

OPNET's simulation kernel (SK) can be considered the master scheduler and the master clock within OPNET simulations. OPNET is a discrete time, event driven system. The time axis within an OPNET simulation is referred to as `sim_time()`. A `sim_time()` equal to 0.0 indicates the beginning of the simulation. As simulations are executed within OPNET, `sim_time()` advances and there are a series of events which become scheduled to occur at different times throughout the simulation. Typical events might include the sending of a packet every X number of seconds, sampling a queue size

periodically, decrementing a counter or a number of other events the designer has defined. The SK is responsible for scheduling these numerous events and ensuring they are executed at the scheduled `sim_time()`.

The various scheduled events are typically executed by the invocation of different processes which define the process modules; the process of *despreading* is executed by the invocation of the PN\_DESPREADER process module shown in Figure A.2. Processes are typically invoked into execution by one of two methods; 1) `sim_time()` reaches the time the process is scheduled to be invoked, and the process is automatically invoked into execution, or 2) OPNET's SK alerts the process by sending an **interrupt** to the respective process via an input stream. The interrupt delivered to the process invokes the process into execution, and the functions of the process are carried out according to the definition of the process. From the designers perspective, interrupts are the most common method of invoking processes into execution.

The focus of modeling in OPNET is in defining the process models (processes) which support and implement the node model. The process models are implemented as a Finite State Machine. The Finite State Machine is defined by completing a state transition diagram which defines the various states of the process and the transitions that interconnect each state. Figure 5.2 portrays this model's PN\_DESPREAD process. Figure A.3 portrays the same process as viewed from within the OPNET graphical environment.

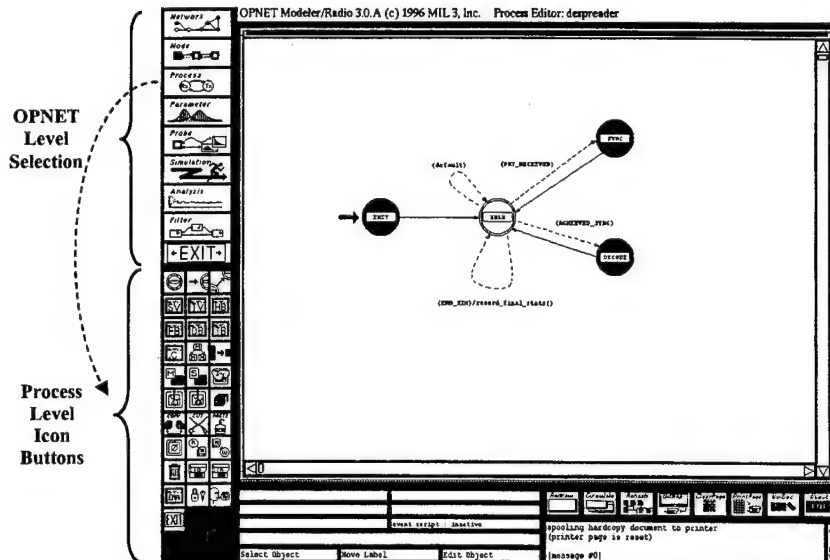

Figure A.3. OPNET View of PN\_DESPREADER Process Model

## C. DEFINING THE PROCESS

### 1. OPNET's Graphical User Interface (GUI)

As seen from Figure A.3, the PN\_DESPREADER process consists of four states. The actions performed within each state are dictated by the designers source code (written in C). In completing the source code for a process, the column of icon buttons on the left side of Figure A.3 play an important role.

The icon buttons Network, Node, Process, Parameter, Probe, Simulation, Analysis, and Filter remain visible in the OPNET window throughout execution of the OPNET program. These icon buttons determine the level (Network, Node, Process) at which the designer will work, or they allow the designer to define Parameters, Probes, Simulations, perform Analysis', and define Filters. The reader interested in these areas is encouraged to consult the OPNET user manuals for a detailed description.

The icon buttons on the lower half of the column are specific to the OPNET level which is in view. For example, selecting the Process icon button from the level selection indicates the designer wishes to work at the Process level within OPNET, and is thus presented with the process level icon buttons as shown in Figure A.3. A magnified view of these icon buttons is shown in Figure A.4.

The process level icon buttons are used for writing the C source code which defines the behavior of the process. Selection of either of the HB, TV, SV, FB, DB, or TB icon buttons will invoke the OPNET editor from which the designer enters the relevant C source code. The HB icon button is used for defining the *header block* of the source code. The TV icon button similarly defines the *temporary variables* of the process. The SV icon button defines the *state variables*, and likewise FB defines the *function block*, DB defines the *debug block*, and TB defines the *termination block* for the process.

**Figure A.4. Process Level Icon Buttons**

The *header block* is similar to a C include.h file; **#include** <> statements and **#define** statements are likely to be coded in the header block. Temporary variables are declared in the *temporary variables* block and are not persistent variables, they exist only during the current invocation of the process. State variables are declared in the *state variables* block. They are persistent and retain their value from one invocation of a process to the next. For example, this despreader process is invoked every time a packet is received at the receiver. Any defined temporary variables are persistent only for the processing of this specific packet. Any state variables are persistent for all packets, as state variables are persistent throughout the simulation. A loop counter is an example of a common temporary variable. State variables are similar to static variables in C. Accumulators are a common example.

The *function block* is where the designer defines the various functions used in the process. The functions are typically called from one of the states, but can of course be called from another function. A common approach is to minimize the code within the states so that they are defined primarily by a series of function calls, and to off-load the bulk of the processing to the various functions defined in the function block. The *debug block* and the *termination block* will not be discussed here.

## 2. Forced and Unforced States

There is significance to the different color shading of the states shown in Figure A.3. States within OPNET are either *forced* or *unforced* states. Unforced states are transparent in color, forced states are opaque. A forced state is synonymous to an atomic instruction; it allows no interruptions during its execution. A forced state controls the simulation until it has completed its actions; it cannot be interrupted by the SK. An unforced state, on the other hand, returns control of the simulation to the SK once the process has entered an unforced state. A process which is in an unforced state is merely waiting another invocation call from the SK.

Once the SK has regained control of the simulation from the process (indicating the process is in an unforced state), the SK is free to invoke other processes of the simulation. The key difference between forced and unforced states is that there is no time lapse between entering and exiting a forced state; all actions within a forced state are essentially executed at the same time. With an unforced state, the time between entering and exiting the state is determined by the overall simulation and the different processes involved. The transparent IDLE state indicates it is an unforced state. The remaining opaque states indicate they are forced states, and will not be interrupted by the SK until they have completed the processing they are defined to perform.

As an example of the above discussion, let us consider the despreader process defined by the state transition diagram of Figure A.3. At the beginning of the simulation, the INIT state is evaluated and initialization of the process is performed. Chapter V outlines the actions performed in this particular INIT state. As the INIT state is a forced state, all actions within this state will be performed at the beginning of the simulation without any interruption from the SK, and without any elapsed time. Upon completion of initialization, the process is forced into the IDLE state. As the IDLE state is an unforced state, control of the simulation returns to the SK, and as no time lapse was incurred during the initialization,  $\text{sim\_time()} = t_0$  indicating the simulation time clock ( $\text{sim\_time()}$ ) has not advanced.

Upon regaining control of the simulation from the despread process, the SK checks the event list. The SK determines the next scheduled event and the time that this event is scheduled to occur. The SK will then notify the relevant process at the appropriate time. The SK's notification to a process is typically performed by delivering an interrupt to the respective process.

### 3. A Packet Flow Example

Consider the flow of a packet from transmission to reception. At some point in time the transmitter transmits a packet. The packet is evaluated by the pipeline stages, and the SK determines the time at which the packet is scheduled to arrive at the receiver, say  $t_{arrival}$ . The SK then schedules a stream interrupt (OPC\_INTRPT\_STREAM) to be delivered to this process at this same arrival time,  $t_{arrival}$ . At  $\text{sim\_time}() = t_{arrival}$ , the SK delivers a stream interrupt to this despreader process. This delivered interrupt will invoke this process into execution (assuming the process is in an unforced state).

We have seen where the despreader process performed the initialization functions at the beginning of the simulation, then transitioned to an IDLE state. Thus, at the time that the SK delivers an interrupt to this process ( $\text{sim\_time}() = t_{arrival}$ ), the despreader process is 'resting' idly in the unforced IDLE state. Within the header block of this process, we have the following definitions:

```
/* Header Block Definitions */  
#define SYNC_ACHIEVED 1  
#define PKT_RECEIVED (op_intrpt_type() == OPC_INTRPT_STREAM)  
#define ACHIEVE_SYNC (op_intrpt_type() == OPC_INTRPT_SELF &&  
                    op_intrpt_code() == SYNC_ACHIEVED)
```

The SK delivered interrupt invokes the execution of this PN\_DESPREADER process. Thus, at  $\text{sim\_time}() = t_{arrival}$  this despreader process begins execution. Upon execution, the process determines that PKT\_RECEIVED evaluates to a TRUE condition (the interrupt just delivered is equal to a *stream type* interrupt) and will thus transition to the SYNC state (see Figure A.3).

As the SYNC state is a forced state, it will execute the code defined within the SYNC state without interruption from the SK. The source code implementing the SYNC state is similar to:

```

/* Sync State implementation code */
packet = get_packet_from(incoming_packet_stream); /* get the incoming packet */
do{
    for(ix = 0; ix < upper_limit_1; ++ix) {
        for(jx = 0; jx < upper_limit_2; ++jx) {
            correlation_value = cross_correlate(packet, pn_code);
            if(correlation_value ≥ sync_threshold) {
                achieved_sync = TRUE;
                store_packet_in_list(packet_safe_keeping_list, packet);
            } /* end if */
        } /* end inner for loop */
    } /* end outer for loop */
} while (!(achieved_sync || all_pn_codes_have_been_checked));

```

From the above block of code, we see the use of several variables. The loop counters *ix* and *jx* are temporary variables and are declared in the TV block. Likewise, *packet* is a packet pointer (Packet \*) and is a temporary variable. It is also declared in the TV block. The variable *packet\_safe\_keeping\_list* represents a linked list which stores packets that have achieved synchronization. As we need this list to be persistent, it is declared in the SV block as a state variable. The functions *get\_packet\_from()*, *store\_packet\_in\_list()*, and *cross\_correlate()* are defined in the FB of this process.

We see from Figure A.3 that the SYNC state has only one transition leaving the state. This transition is an unconditional transition, which is indicated by the solid line and the lack of any conditional statement above the transition. Upon completion of the actions within the SYNC state (i.e. executing the above block of code) the process unconditionally transitions back to the DECODE state. As DECODE is an unforced state, control of the simulation is then returned to the OPNET SK. The SK will again evaluate the event list, determine the next scheduled event, and send an interrupt to the respective process, and the simulation continues in a like fashion.

#### D. SUMMARY

Here we have provided an overview of the OPNET modeling software. We reviewed several OPNET specific terms. We noted that the OPNET simulation kernel

(SK) might be considered the master scheduler and the master clock, and we noted that the SK communicates with the different processes by sending stream interrupts to the respective process. We outlined the differentiation between forced and unforced states and reviewed how control of the simulation is passed to the process while within a forced state, and is then returned to the SK once the process returns to an unforced state. With this overview, the reader is provided a basic understanding of the OPNET modeling software package.

## **APPENDIX B. PIPELINE SPECIFICS**

The objective of this appendix is to present an overview of the OPNET pipeline stages and review the details of the Interference, the SNR, the BER, and the Error Allocation pipeline stages. This appendix is intended as a supplement to Chapter IV and is not written to stand alone; it should be consulted as necessary after reviewing Chapter IV. We assume the reader is familiar with the OPNET modeling software and has reviewed Appendix A as necessary.

### **A. PIPELINE STAGES OVERVIEW**

OPNET Pipeline stages are user coded (or OPNET defaults) C functions that are used to model an RF channel. Most of the stages are executed sequentially as is implied in Figure 4.1. The stages query information from packets in a variety of ways, which we will soon show. In executing several of the stages there is no time lapse incurred, i.e. the invocation of several stages are scheduled for the same time and are 'stacked' on each other in the event list. Simulation time 'stands still' during the sequential execution of these stages. The SK manages the scheduling and invocations of the stages, and the designer need only be concerned with the actual coding of the C functions to properly characterize the channel according to the user's model.

When a process sends a packet through a radio transmitter, the SK realizes the need for the pipeline stages. The SK will schedule in the event list a number of function calls to invoke each of the pipeline stages at the appropriate time. When the SK invokes a pipeline stage, the packet to be evaluated is automatically passed to the user defined C function which implements the pipeline stage.

An OPNET specific term used throughout Chapter IV is TDA, which represents Transmission Data Attribute. TDA's are fields within the packet which are used to store a variety of informational values pertaining to the packet. TDA's have a bit length of zero, meaning the length of the TDA field is not considered in any pipeline calculations. TDA's are place-holders of information. There are numerous TDA's defined within OPNET. Most of the TDA's are for the exclusive use of the SK. Most all the TDA's can be read, but only a small minority of them can be written to by the pipeline stages.

Packets do not have TDA's until they are transmitted from a radio transmitter (meaning they can be queried in the receiver process, but they don't yet exist in the

spreading process). The SK establishes and sets the appropriate values for a number of TDA's once a packet has been sent from a radio transmitter, and not until.

As pipeline stages are invoked by the SK, the pipeline stages perform their requisite calculations and insert the result(s) into the respective TDA of the packet. Later stages will often make their calculations based on the value(s) set in a particular TDA from a previous stage. Thus, the pipeline stages can be considered sequentially executed C functions which read and set values of the packet's TDA's. The inclusive set of pipeline stages allow the designer to completely model an RF channel and to report the channel's characterization via the TDA's.

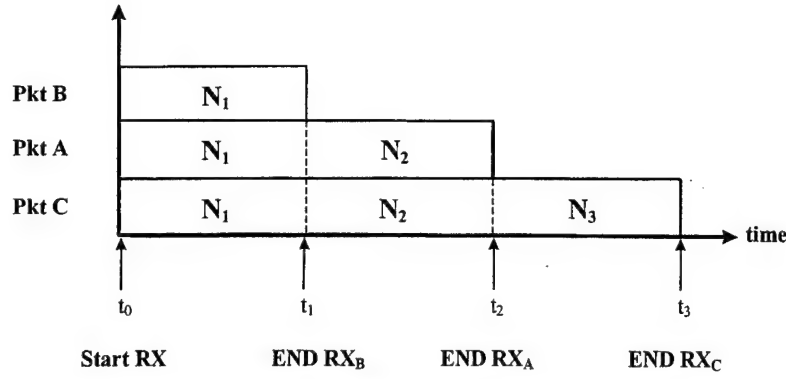

## **B. INTERFERENCE AND SNR SPECIFICS**

In this section we review the details of implementing the Interference, the SNR, the BER, and the Error Allocation pipeline stages. To properly model this proposed system, it is critical to fully understand how these pipeline stages are invoked and at what respective times they are invoked by the SK.

### **1. Interference Noise Calculations**

The Interference Noise stage is the only pipeline stage which receives two packets from the SK. Upon invocation of this stage, the SK automatically passes both packets of interest to this pipeline stage.

Interference as defined here indicates simultaneous reception of packets. Interference is caused by the overlapping reception of packets at the receiver and occurs for a packet in two instances: 1) a packet is being received and another packet arrives, or 2) a packet arrives when another packet is being received. Figure B.1 depicts an example of three simultaneously arriving packets. In this example, this pipeline stage will be invoked three times. The reasoning follows.

**Figure B.1. Multiple Packet Reception and Respective Noise Levels**

The SK orders simulation events in an arbitrary manner. There are typically several events scheduled simultaneously. In the above example, at least three events are scheduled for  $time\ t_0 = \text{START\_RX}$ ; the arrival events of each packet. Due to the arbitrary ordering of events, the SK must select one of the packets as the first received. Simulation runs indicate the SK selects the packet with the lowest numerical *packet id* (*pkt\_id*) as the first arriving packet. *Packet id* is an internal attribute defined by the SK. The designer cannot set or modify this attribute.

Consider for example Figure B.1. Here we assume  $\text{pkt\_id}(\text{B}) < \text{pkt\_id}(\text{A}) < \text{pkt\_id}(\text{C})$ . In this example, the Interference Noise stage will be invoked first with packets B and A due to packet A's interference on B, again with packets B and C due to packet C's interference on B, and finally with packets A and C due to packet C's interference on packet A.

Note also that when a packet completes reception ( $\text{END\_RX}$ ), the SK automatically subtracts the completely received packets accumulated noise power from any packets still being received. In the above case for example, this pipeline stage will not be re-invoked at  $time\ t = t_1$ . The interfering noise power TDA ( $\text{NOISE\_ACCUM}$ ) of packets A and C will however reflect the correct noise power due to interference:  $N_2 = P_r$ , and likewise  $N_3 = 0$  as there is no interference during this packet segment. Equation (4.8) shows the noise power calculation employed by this model.

## 2. Signal-to-Noise Ratio

The SNR pipeline stage is invoked for packet a due to one of three conditions: 1) a packet **begins** reception, 2) a packet is being received and another packet arrives, or 3) a

packet is being received and another packet completes reception. Essentially upon a packets arrival at the receiver, or upon a collision.

For the example shown in Figure B.1, the SNR stage will be invoked for packet A three times (assuming the SK assigns packet B the lowest numerical packet id). Packet B will invoke the SNR stage first at *time*  $t = t_0$  due to condition 1 (B arrives); a second time at *time*  $t = t_0$  due to condition 2 (A arrives), and a final time at *time*  $t = t_0$  again due to condition 2 (C arrives). Similarly, packet A will invoke the SNR stage first at *time*  $t = t_0$  due to condition 1 (A arrives), and a second invocation at *time*  $t = t_0$  due to condition 2 (C arrives). The third invocation is at *time*  $t = t_1$  due to condition 3 (B completes reception). Finally, packet C will invoke the SNR stage first at *time*  $t = t_0$  due to condition 1 (C arrives), a second invocation at *time*  $t = t_1$  due to condition 3 (B completes reception), and a third invocation at *time*  $t = t_2$ , again due to condition 3 (A completes reception).

Essentially, the packet is assigned a segment SNR based on the background noise during the segment interval. This models' implementation determines SNR strictly based upon the background noise  $N_b$  as shown in Chapter IV, and the differing levels of interference noise,  $N_i$ , are not utilized within this SNR pipeline stage. We include the previous discussion as it applies in the general case. Although this model employs packets of equal length, it can be employed for packets of varying lengths.

Recall upon an interfering packet completing reception, the SK will automatically subtract its received power from the noise accumulator (NOISE\_ACCUM TDA) of any packets still being received. Effectively  $N_2$  and  $N_3$  from Figure B.1 are internally modified by the SK and the values reported in this pipeline stage will reflect the noise level due only to interfering packets.

Prior to leaving the SNR pipeline stage, a time stamp is placed on the packet. This time stamp is set in the TDA SNR\_CALC\_TIME and indicates the last time at which this particular packet visited this stage. In essence, it defines a packet segment of differing SNR levels. The SNR is held constant over the duration of any one segment. This parameter is necessary in the later BER and Error Allocation pipeline stages.

The primary contribution of determining the SNR is its effect in determining the bit error rate (BER) of the channel. The BER is a key benchmark in channel analysis, and we now consider this model's implementation of the BER pipeline stage.

## C. BIT ERROR RATE SPECIFICS

Arguably one of the most critical components of channel characterization is the BER. The BER may be a function of several parameters, depending on the channel model used. The BER may be a function of the type of signal modulation used, a function of interference noise encountered over the channel during transmission, or a function of the amount of white noise present, or some combination. Determining the channel BER and properly injecting the errors accordingly are key focal points of this effort.

### 1. BER Pipeline Stage Invocation

The relevance of the discussion in the interference stage concerning the timing of pipeline stage invocation may become more obvious with what follows. Understanding the timing of the pipeline stage invocations is critical in determining the correct BER.

Similar to the interference noise stage and the SNR stage, the BER pipeline stage may be invoked for a valid packet for one of three reasons: 1) the packet **completes** reception, 2) the packet is being received and another packet arrives, or 3) the packet is being received and another packet completes reception. With the continued assumption that packet B is assigned the lowest pkt\_id by the SK, and following the discussion of the interference and SNR stages, we realize the specific times each of the following packets will invoke the BER stage. Viewing Figure B.2, we can ascertain from the previous discussion and the conditions just listed that each of the three packets will

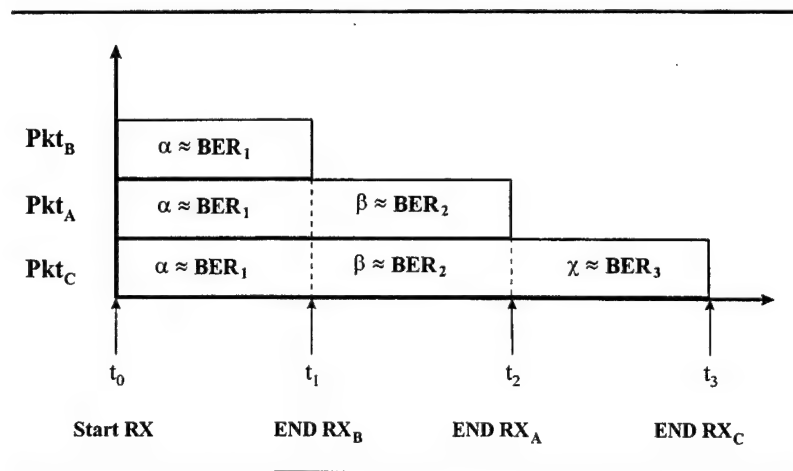

Figure B.2. BER Pipeline Stage Invocation Events

invoke the BER stage three times. Table B.1 offers a synopsis of the times and the condition (number 1, 2, or 3 above) which is met to cause the invocation. As the BER is a function of the number of  $K$  interfering users, we require the instantaneous count of interfering users on any particular packet segment.

The interference stage informs us of the number of interfering users, but only at

**Table B.1. BER Pipeline Stage Invocation Times and Conditions**

Packet	Invocation Times	Respective Conditions
B	$t_0, t_0, t_1$	2,2,1
A	$t_0, t_1, t_2$	2,3,1
C	$t_1, t_2, t_3$	3,3,1

the onset of interference. Packets may invoke the interference stage numerous times, but only at *time*  $t = t_0$  (START\_RX). Too, OPNET's SK will automatically subtract the power contribution ( $P_i$ ) of packets completing reception from any packets still being received. As the BER is not strictly a matter of SNR, we must determine WHY this stage is invoked each time the SK invokes this pipeline stage.

## 2. Conditions of Invocation

We implement this stage of the pipeline by evaluating three different times for each packet; 1) *time*  $t = \text{START\_RX}$  (time of starting reception), 2) *time*  $t = \text{END\_RX}$  (time of ending reception), and 3) *time*  $t =$  the current simulation time. Recall that each packet maintains numerous TDA's. START\_RX and END\_RX are two of these, and the SK automatically determines and sets these values in each respective packet. With the intent of fully clarifying the implementation, let us walk through the BER calculation for packet B (we continue our assumption of packet B having the lowest id):

**Case 1:** The first time we see packet B is at *time*  $t = t_0$  due to condition (2), packet A arrives at the receiver. We check the SK master clock, `sim_time()`, and we check the packet's START\_RX. We see they are the same, thus BER = 0. This is accurate in that we are at the leading edge of the packet, the segment length = 0, and thus there are no bits in error.

**Case 2:** The next time we see packet B is again at *time*  $t = t_0$  due to condition (2), packet C arrives at the receiver. Again, a time check indicates we are just starting reception; BER = 0.

**Case 3:** The final time we see packet B is at *time*  $t = t_1$  due to condition (1), packet B completes reception. We check the SK master clock and we see that we are past START\_RX. This indicates either we have finished reception (condition (1)), or another packet has completed reception and forced this packet to invoke this pipeline stage again (condition (3)). We must determine which of the two cases holds true.

Next we check packet B's TDA (NUM\_COLLIS) to determine if the packet suffered any interference from the interference stage. As the BER is a function of  $K$  (the number of multiple users), we now have  $K = \text{NUM\_COLLS} + 1$ , the one being ourselves. From this, we can determine the packet's BER as shown in Chapter IV. The determined BER is set in the respective packet's TDA. Prior to leaving this stage however, we must determine why this packet invoked this stage.

If the current time is equal to END\_RX, then we are here due to condition (1). No action is required, as this packet is completely received and the BER is properly determined. If the time comparison shows we are not finishing reception (current time < END\_RX), then we must be here due to condition (3): another packet has completed reception. This indicates we will invoke this stage at least once more. But this packet now has one less interfering user. We must adjust the TDA (NUM\_COLLIS) to reflect this. We decrement NUM\_COLLIS by one to reflect the fact that an interfering packet has been completely received and is no longer interfering with this packet's reception. Note, the BER was determined prior to decrementing NUM\_COLLIS.

We can follow this logic through for packets A and C and we will find the results are the same. Rather, we offer a summary in the concise form of simple pseudocode:

```

if(time  $t$  == START_RX)
    BER = 0
else
    BER = f(K), where  $K = \text{NUM\_COLLS} + 1$     /* Rayleigh or SGA dependent */
end if
if(time  $t$  < END_RX )                        /* another packet finished */
    decrement NUM_COLLIS                      /* set it up for the next visit */

```

Each invocation of the SNR stage defines a packet segment which will have its own segment SNR and segment BER as shown in Figure B.2. As we have seen in some cases, the segment length is zero. In others, it may be equal to the packet length. What is critical is determining the correct value of  $K$ .

The next objective is to inject the errors within each packet as determined from the BER stage. The Error Allocation pipeline stage is the BER injector, and is the next pipeline stage for review.

#### **D. ERROR ALLOCATION SPECIFICS**

The OPNET default error pipeline stage provides an error allocation approach which is accurate and efficient in terms of simulation time requirements. The OPNET manuals offer a detailed discussion of the algorithm used, and that approach is quite satisfactory for the general case [17]. In this model, we necessarily part from the default stage in that we must specifically test each bit of the packet against the probability of an error.

The majority of the necessary work has been accomplished in previous stages. The packet that arrives to this stage will have no less than one SNR segment and no less than one BER segment. Recall that each visit to the SNR stage defines a packet segment. Equivalently, each SNR pipeline stage invocation will cause an invocation of the BER pipeline stage which also defines a packet segment.

What remains to be done is to physically inject errors according to the determined BER. The BER was set in the packets TDA (BER) from the previous stage. This model implements this Error Allocation pipeline stage by querying the set BER and determining the effected packet's segment length. We sequence through the respective packet segment randomly inverting bits throughout the segment. The pseudocode showing this approach is presented in Chapter IV.

#### **E. SUMMARY**

In this appendix we provided an overview of the OPNET pipeline stages and reviewed the specifics of the Interference, the SNR, the BER, and the Error Allocation pipeline stages. To correctly model this system, the designer must fully understand the timing of the invocations of the different stages, as they greatly impact the model.

## APPENDIX C. CONSTANT TRAFFIC GENERATOR SOURCE CODE

In this and the following appendices, we list the source code implementing this model. The code is commented throughout where appropriate.

/* This model is intended to model a CDMA SS system. Thus, we want to allow
/* simultaneous multiple access within this receiver. In our SYNC state, we
/* do several things, which we will see, but a note is worth explaining now.
/* We'll have to correlate each packet that is received to determine if we can
/* decode the pkt. Errors induced in the error.ps.c pipeline stage could render
/* the pkt as junk of course. Assume the case of simultaneous reception of two pkts.
/* Assuming they both were correlated fine and were determined as 'good' pkts, we
/* need to also determine if they were sent using the same or different PN Codes.
/* If the same, then we have a 'true collision' and the pkts get destroyed. If
/* different codes, then we're ok. As pkts will assumingly arrive at the receiver
/* at the same time (equidistant xmtrs, slotted MAC), we need to maintain all of
/* the pkts until we have processed all that were simultaneously received. Once all
/* have been processed, we check for duplicate PN codes and deal with those pkts then.

/* we accomplish this by placing the pkts in a linked list. the below array is the
/* array of pointers pointing to the linked lists. The indices of the array will
/* match the index of the pn sequence which the received pkt used, based on the
/* polynomial that was used in the transmitter. The polynomials are defined in the
/* header block of this process, in code_matrix[][].

/* For example: Assume two pkts were received simultaneously, and both used the first
/* polynomial, R(3,7) to determine their pn sequence. The end result is
/* array_of_ptrs_to_packet_list[0] will point to a linked list, and the elements of
/* this list will be the pkt pointers of both received pkts, size of list = 2.

/* once all the simultaneous received pkts have been gone through, we merely go
/* through this array and find the size of each list. If the list has N > 1 elements,
/* this indicates N pkts were simultaneously received that had the same PN code.

## DECODE State

```
/* we're here only because we were able to achieve synchronization on the */
/* received spreaded packet in the SYNC state. If sync was achieved, the received */
/* pkt was placed inside a list (acutally an an array of list pointers). As the */
/* SYNC state will be invoked for each received pkt at time = END_RX, we need to */
/* to maintain all pkts that passed synchronization until all received pkts have */
/* have been processed. Once OPNET has processed all the events in the event list */
/* (all the STRM_INTRPT's), we can then safely /* move to this DECODE state and */
/* attempt to decode the data of the received pkt. We now have an array of list */
/* pointers, each pointing to a list of pkts which were synchronized with the same */
/* PN code sequence (if any). If there are more than one pkt in each list, we have */
/* a collision caused by multiple PN code sequences. */

/* now that we are here, we'll need to correlate the mac and data pkt and extract */
/**/
/* the information. We know from the correlation process of the synchronization bits */
/* what particular characteristic polynomial and what initial register load was */
/* used by the transmitter. That info has been maintained in our state variables. */
/* From that info, we have also already discovered our PN sequence that was used */
/* to spread the information on the transmitter end. At this point, we have a pkt */
/* of spreaded information which has been stripped of the synchronization bits. */

/* Recall our array_of_ptrs_to_packet_list[] was declared to hold pointers to a */
/* list of pkt pointers. We need to loop through the array, check each list pointed */
/* to by the array element. If there are more than one elements in each respective */
/* list, this indicates we had packets with the same PN sequence. Deal with it. */

    /* We're in this branch because there was only one pkt in the linked list,
    /* which indicates there were no PN Collisions. The pkt currently has a sync
    /* header and a mac header prefacing the information data bits, and all of this
    /* has been spreaded by our PN sequence in the transmitter. We recovered this
    /* pn sequence in the SYNC state (or we wouldn't be here). What is left to do
    /* is to strip the sync bits, strip the mac header bits, then despread
    /* (correlate) the data bits and attempt to recover as many as we can. The
    /* error.ps.c pipeline stage was our error injector. Based on the determined
    /* BER, this error pipeline stage may very well have ruined some of our bits.
    /* Recall that our pkt only contains a pointer to the spreaded bits in memory.
    /* Rather than actually stripping the sync and mac header bits from the 'pkt'
    /* we'll pass this pkt to our correlate_data_bits() function which will:
    /* extract the spreaded_bits_ptr from the pkt, skip past the sync and mac
    /* header bits, then correlate the bits from that point on.
    /* The correlated data values will be returned in data_array[]. The memory
    /* allocated and pointed to by our memory ptr *spreaded_bits_ptr will be
    /* deallocated within correlate_data_bits()

    /* first, get (effectively removing) the pkt from the linked list. we can
    /* either access or remove an element in the list. Accessing allows
    /* non-destructive querying values of the pkt, whereas removal will actually
    /* remove the item from the list. wow, what a concept huh.

    /* there should only be one packet in the list pointed to by
    /* array_of_ptrs_to_packet_list[ix] at this point. get a pointer to it.

    spreaded_data_pkptr = (Packet*) op_prg_list_remove(array_of_ptrs_to_packet_list[ix],

        /* we should now have an array containing the recovered transmitted data
        /* bits (assuming the signal was legit). we'll 'repacketize' these data
        /**/
        /* data bits and send them on their merry way. In this case, their merry
        /* way is considered to be the next protocol layer, like maybe the MAC
        /* layer. Our MAC layer consists of a SINK process which will just destroy
        /* the pkt. We could do it here as well, but our intent is to complete this
        /* entire path from tx to rx. With this approach, we can easily use a module
        /* other than SINK for our next process, and minimal recoding is required.
        /* This keeps this implementation somewhat cohesive.

        /* number_of_data_bits tells us how many data bits are in the pkt. */
        recovered_data_pkptr = packetize_recovered_data(data_array, number_of_data_bits);

```

```

    if(recovered_data_pkptr != (Packet *) OPC_NIL)
        op_pk_send(recovered_data_pkptr, TO_HIGHER_LAYER);
    else
        op_sim_message("ERROR:DESPREADER:DECODE STATE:",
            "Unable to recover data bits. Your data from this packet is lost.");
}
else; /* else the SYNC state inserted a null pkptr into our list, the jerk */
/* who knows why. now action required, as there is nothing to destroy */

} /* end of: else if(number_of_packets_in_list > 0) */
} /* end of: ix < NUMBER_PN_CODES */

/* we have effectively recovered any data pkts that were received collision free. */
/* this includes packets that suffered MAI from other arriving pkts w/different PN */
/* codes likewise, we have destroyed any pkts that were collisions in the sense */
/* that they had the same PN sequence. This process was invoked due to a self */
/* interrupt scheduled in the SYNC State. */
/* Thus, there are as many interrupts waiting to invoke this process */
/* as there were multiple pkts received. We're probably best off by going through the */
/* event list and removing the remaining events scheduled for this process. All the */
/* necessary work to recover all non-colliding packets and interfered packets has been */
/* been done in this first invocation. As well, all colliding packets have been */
/* destroyed, counters adjusted, and the linked list(s) pointed to by */
/* array_of_ptrs_to_packet_list[] has been gone through, destroying any packets that */
/* were in this list, as they have all been dealt with accordingly. Good housekeeping */
/* suggests we clean up our mess. thus, we'll loop through the event list checking for */
/* any remaining INTRPT_SELF's. If they are of code SYNC_ACHIEVED, then they were */
/* scheduled in the SYNC state. There is at least one other INTRPT_SELF currently */
/* scheduled, an END_SIM interrupt, so don't kill it. The only apparent danger, at */
/* this stage, is that there could have been arriving packets in the next slot time */
/* that have been through the SYNC state, and thus have scheduled a INTRPT_SELF for */
/* themselves. */

/* However, the interrupt scheduled in the SYNC state is with a nominal time delay, */
/* call it tau, after completing the SYNC state. as long as tau < guard time, */
/* we should be safe. As a complete check, we can check the approximate scheduled time */
/* of the events, and cancel only those that are scheduled for about this time, which */
/* would be those remaining interrupts scheduled in this slot time. */

/* now I'm thoroughly confused. maybe the code will be clear. */

clean_up_event_list();
